At Eiselberg's clinic, a patient presented himself because of a very disfiguring swelling of the nose. The patient said that when two years old he had fallen on the street, striking the root of the nose. A short time afterward, the skin there and on the bridge of the nose became red, and remained so until he was eight years old. In that year a soft swelling, about as big as a pea, appeared at the root of the nose, and slowly increased in size. Since then the nose, the upper lip, and the right cheek had gradually become swollen. The disfiguring form of the swelling, which suggested the snout of a tapir, included the nose, the right half of the upper lip, and the right cheek. The prominence on the left could be recognized as nose, while the whole remaining part of the swelling belonged to the right ala nasi. The right nostril was larger than the left. The whole swelling was very soft, elastic, compressible, and clearly showed a pulsation, which disappeared on compression of the right carotid. If the patient leaned forward, the swelling was larger and harder. In the skin could be seen numerous dilated vessels. It seemed like an angioma racemosum, possibly of traumatic origin. In the bony and cartilaginous framework of the nose, were slight elevations and depressions which could be reduced by pressure on the swollen blood-vessels. There the patient felt pain. The treatment consisted in a wedged-shaped excision of the tumor, by which, in several sittings, little by little the swelling was reduced and the nose and lips were given a less disfiguring appearance.

Dr. Budinger, in the Society of Physicians, showed a lung sequestrum, the size of a child's fist, found in an operation for lung abscess. The patient, a civil officer, forty years old, was seized with a chill, after which a fever developed which was supposed to be typhoid. He first began to cough in the fifth week, after this the lung abscess became evident, and its extent could be clearly seen in the Röntgen picture. When the abscess was opened, with rib resection, there was found a sequestrum of the right middle lobe. In an angle of this lay a piece of an ear of grain, 3 cm. long, concerning the entrance of which the patient could give no information. The lack of symptoms during the course, and the absence of all lung symptoms in the beginning, were striking. The sequestrum was characterized on two sides by a smooth surface which had probably been connected with the lung surface, and it was necessary to seek an explanation of the occurrence in the fact that the suppuration from the foreign body spread out slowly, and extended in a plane having on one side the base, and on the other the anterior part of the lung, which caused a circumscribed empyema. In this way, a piece of the lobe was bathed in pus, and only remained in connection with the rest of the lung tissue by a thin pedicle, which included a bronchus. The sequestrum contained air.

Dr. Haberer presented from the surgical clinic a cured case of injury to the transverse sinus. The patient, fifty-five years old, had received a stab wound on the back of his head, by which a piece of the tabular part of the occipital bone, the size of a crownpiece, was broken off. Immediately on the removal of this piece of bone with the dressing forceps, the blood flowed freely from the transverse sinus through the wound in the dura. The hemorrhage was stopped by packing. This wound, as also a stab wound perforating the right upper arm, on the posterior aspect, close to the bone, healed without complication.

Dr. Alois Monti has recently attempted the cure of whooping-cough in children by an entirely new method. The children were brought once a day into a room where they sat for three-quarters of an hour to an hour in the midst of camphor and naphthalin vapor. No bad results have as yet occurred, but on the contrary the lighter cases have been entirely healed in from three to four weeks, and the more severe ones in from four to six weeks.

In Schotter's clinic attempts have been made on a series of patients to accomplish the cure of tuberculosis by the inhalation of vaporized Koch's tuberculin. The patient breathes through the mouth, and in such a way that none of the vapor can enter the nose. He breathes quietly and deeply, the inhalation lasting from five to ten minutes. The observations extended to twenty-eight patients of different ages and sexes, and it appeared that the inhalation of tuberculin gave the same results as its injection.

On June 21, in the presence of the emperor, the ministers, the entire staff professors and "docenten," the cornerstone of the new general hospital was laid. The celebration took place in the grounds of the present hospital. In his address to the emperor, the minister of education gave the plan of the hospital and clinic in Vienna, and characterized the proposed new building as an institution "which, with all the equipments of modern times, should contribute to the blessing and honor of the State and of the city, an institution which will offer to suffering humanity efficient help, and, moreover, to science, which is so cramped in the present quarters as to suffer serious injury, it secures a new and enduring life." After Professor von Escherich had sketched the history of the new university institution, the emperor expressed his pleasure at being present for the celebration saying that "the remarkable successes which had been obtained in the art of healing in recent times through tireless investigators, justify the demand of these workers for greater facilities and the aid of every technical appliance in the prosecution of their studies. Much more will thus be accomplished for the welfare of suffering humanity and for the honor and glory of science.

The new hospital will be erected on a site of more than 40,000 square meters. Seventeen clinics and a dispensary will be built on the pavilion system. Further, there will be an institution for the study of pathological anatomy, and administration buildings. Each pavilion will be 120 to 130 meters long and two to three stories high, and, with its wards, operating and lecture rooms, and small laboratories will form a kind of special hospital. Also isolation pavilions are planned. Thus the new hospital will contain about forty buildings, separated from one another by paths and gardens. There will be two obstetrical and gynecological clinics with isolation and reception buildings (four buildings); children's clinic with six isolation buildings for the different infectious diseases (seven buildings); laryngological clinic (one building); three medical clinics and dispensaries, with three isolation buildings (seven buildings); ear clinic (one building); two dermatological clinics (two buildings); orthopedic clinic (one building); two eye clinics (two buildings); two surgical clinics (two buildings); two clinics for mental diseases with isolation buildings (three buildings); pathological anatomy, legal medicine, medical chemistry, and the chapel with the morgue (one building); and the institute for dentistry, radiotherapy, photography, etc. (one building). There will also be in different parts of the park eight administration and work buildings, namely, the porter's lodge, the reception building, the building

for administration and direction, the dwelling house for the director, the large work building with a great kitchen, a conservatory, and the Sisters' house, for the nuns consecrated to the care of the sick. On the ground floor of each clinical pavilion are to be the out-patient departments, where clinical instruction will be given to students. On the first floor are situated the lecture and operating rooms; further, in two or three wings, the wards. The new hospital will be finished in about eight years. It will be, as was the Josephine, 120 years ago, the most complete of its time, and serve as pattern to other cities which still have old hospitals and clinics.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 4, 1904.

Operations upon Benign Diseases of the Stomach at Boston City Hospital and Massachusetts General Hospital, 1898-1903 Inclusive.—F. B. Lund, E. P. Joslyn, and F. T. Murphy report 43 operations for chronic gastric ulcer, pyloric obstruction, and acute gastric dilatation, 18 operations for perforation of gastric ulcer, and 10 operations for gastric hemorrhage. In the first class of operations there were 11 deaths, 16 entire recoveries, 7 relieved, 9 not relieved, and 10 secondary operations required. Of the 18 operations, 13 died, 5 recovered, and 2 secondary operations were required. The 10 cases of hemorrhage all terminated fatally. They conclude that (1) Surgical intervention in gastric hemorrhage should be considered at once in consultation of physician and surgeon. In females under thirty years conservatism is desirable. In cases in which life is threatened gastroenterostomy should be done at once. (2) Mortality in operations for perforation is chiefly dependent on the length of time after the perforation occurs when operation is undertaken, and the virulence of the infection. (3) In chronic ulcers or strictures of the pylorus, postponement of operation when indicated is dangerous, owing to the possibility of hemorrhage, perforation, and exhaustion. (4) Errors in surgical technique and the choice of operations now known to be unsuitable account for about half the deaths. The 71 cases were operated on by 25 different surgeons. If done by one surgeon better results would be expected.

Journal of the American Medical Association, August 6, 1904.

The Physiology of the Middle Ear.—J. Holinger considers the theories of Helmholtz on the function of the middle-ear apparatus as well as the very simple and clear theory of Zimmermann of Dresden. It rests with physiologists and otologists to decide which theory shall stand or fall; whether in the future we shall consider the whole middle ear as an important adjuvant in hearing, or as a secondary regulating mechanism without which we may very well get along. It has been his conviction that a large number of otologists belong to the latter category, inasmuch as the rule has been made, and widely followed, to remove the mallet and incus and, if possible, the stirrup in radical operations in all cases of chronic suppuration of the middle ear that do not readily yield to treatment.

Another Member of the Dysentery Group.—C. W. Duval gives a brief description of a bacillus in all probability another member of the *B. dysenteriæ* group. The organism differs from all hitherto described stains of the dysentery group in its action on lactose and litmus milk. These distinctions in cultural features are in conformity with the variations in agglutination reaction. The bacillus is identical in morphology and in its action on mannite, dextrose, dextrin, and the more common culture media with the Flexner-Harris strain of *B. dysenteriæ*. The bacillus is agglutinated in high dilution with the blood of typhoid-fever patients, also with the blood of rabbits immunized against typhoid. Likewise, *B. typhosus* is agglutinated with the blood of rabbits immunized to this organism. The production of common agglutins show a close relationship between this organism and the typhoid bacillus. Though this bacillus possesses properties in common with the typhoid bacillus it has, however, more in common with the dysentery. Therefore, in his opinion, it is rightly considered another member of the dysentery group.

Hyperidrosis Pedum and Its Treatment by Baths of Permanganate of Potassium.—Ludwig Weiss advocates a treatment devoid of all dangers and which lacks the unpleasantness of many remedies he enumerates. Irrespective of the severity of the case, he starts with a one-per-cent. solution of permanganate of potassium heated to 104° F. The foot should be immersed in this solution for fifteen minutes, and it is then placed on some dry toweling and allowed to drain. Upon going to bed the foot should be lightly covered. Next morning the whole foot is slightly dusted with the following powder: Permanganate of potassium, 13.0; alum, 1.0; talcum, 50.0; oxide of zinc and calcium, each, 18.0. A daily change of shoes and stockings is desirable. The baths are repeated each night and the average duration of treatment is two weeks. After the third bath the strength of the solution is increased to 2 per cent. At the beginning of the second week, the foot baths should be taken as hot as can be borne. The last three baths should be taken full strength, 60 gr. to 1,000 or two ounces to a quart of water. The advantages of this treatment are: (1) The remedy employed is absolutely devoid of any danger, is painless, and heals the dreaded fissures without the previous painful application of silver nitrate. (2) It can be employed in every stage and form of sweating feet. (3) Relapses are less common than with any other method and rarely appear before the third month. (4) The use of the dusting powder has, in some cases, made the interval even longer. (5) Its action consists in its reducing power and consequent keratization of the epidermis. It stands to reason that it penetrates into the secretory cells of the coil glands, inhibiting or decreasing their physiological overactivity. (6) After desquamation the new epidermis is not sensitive, and walking is not impaired as after the use of chromic acid. (7) The mode of employment—medicated footbaths—is a pleasant one.

Medical News, August 6, 1904.

Conservatism in Otology.—Gorham Bacon advocates conservatism in otological operations, especially in the treatment of chronic purulent otitis media. When an operation is necessary to relieve a condition dangerous to life, it should be done without delay. On the other hand, many cases of otitis media may be relieved by treatment, and never need come to the operating table. If the opening in the membrane is large enough for free drainage, and there is not much dead bone there is little chance of the disease extending to the brain, if properly treated. For this he uses solutions of bichloride of mercury, 1-3000, followed by boracic-acid injections, or iodoform and alcohol. Peroxide of hydrogen should not be used. Exuberant granulations should be removed and free drainage established. In a case with frequent pain, much carious bone, fetid discharge, cholesteatomatous masses, especially if the attic be carious, operation is imperative. Other indications for operation are mastoid inflammation, headache, nausea, vomiting, and vertigo.

Dipsomania and Its Treatment.—William Lee Howard considers dipsomania a functional neurosis, due to autointoxication from faulty metabolism, the result of an unstable nervous system. There is no scientific basis for the idea that it is a disease directly inherited. The author considers the following the rational treatment: He first places the patient on a diet free from proteids, to avoid the formation of excessive quantities of soluble peptones and albumoses, which excite the nervous system. He then institutes an eliminative treatment, giving a daily mild natural water purgative and a Turkish bath twice weekly. After a time these measures may be used less frequently. He uses nitrate of strychnine continuously for a month, and renews it after a rest, continuing the administration for two years or more. At the time of an attack of dipsomania the strychnine is taken in doses of $\frac{1}{60}$ gr. every four hours. Breathing exercises are used to lessen suboxidation. There is no specific for the attacks; it is a physiological question purely, and under the control of the patient. Elimination is the watchword in the treatment.

New York Medical Journal, August 6, 1904.

Appendicitis Associated with Disease of the Tubes and Ovaries.—H. C. Coe touches upon the following points in a brief résumé: Appendicitis is a frequent complication of inflammatory disease of the adnexa. In most cases it is secondary to adnexal trouble, a long appendix in contact with, or adherent to, the right tube or ovary being infected by extension through its wall, or through the lymphatics. The inflammation of the appendix is usually of the subacute type. In a small proportion of cases the infection extends from the appendix to an adherent tube or ovary, or cystoma. The symptoms of the associated conditions are usually determined by the more prominent lesion, but these are referable principally to the diseased adnexa. The diagnosis is made from the history, the location of the pain (above, as well as below, the pelvic brim), and the presence of an induration which can be traced from the appendicular region downward into the pelvis. In acute cases, with an extrapelvic mass, the lateral incision is preferable, with subsequent exploration of the pelvis and vaginal drainage if possible. If the abscess is mainly intrapelvic and easily accessible, vaginal section is indicated. In subacute and recurrent cases a median incision is to be elected. The appendix should be removed whenever the abdomen is opened for pelvic disease, with the exceptions noted.

American Medicine, August 6, 1904.

Treatment of Chronic Internal Hydrocephalus by Lumbar Puncture.—H. Lowenberg reports a case of chronic internal hydrocephalus in which he drew off, by lumbar puncture, 50 c.c. to 60 c.c. of cerebrospinal fluid about once a week, with apparent improvement mentally and physically and some reduction in the size of the head. The treatment covered two months, the child dying of bronchopneumonia complicating measles. He says the following conditions must be present in any case to render lumbar puncture useful: (1) Free communication must exist between the ventricles and the subdural spinal space; (2) the head must be compressible; and (3) the bones must be flexible and there must be no evidence of ossification in the fontanel or the sutures. Ossification is usually well advanced after the second year, therefore treatment must be instituted before this period. Lumbar puncture is preferable to direct tapping of the ventricles, as there is an entire absence of all danger of the untoward complications following the latter.

Occurrence of Framboesia in Natives of the Philippine Islands.—Paul G. Woolley observed a number of cases of framboesia or yaws while on a trip through northern Luzon. They were characterized by sluggish ulcers on the legs, neck, or body, and anæmia. The sores were itchy, but not painful. He excised the ulcer in one case and preserved it for histological examination. The ulcer was shallow, with a firm gray base, a well-defined margin, slight yellowish secretion, and no induration. It was situated below the angle of the jaw and was not painful. The scars of earlier lesions were pigmented, not thickened, and not anæsthetic. There seemed to be no evidence of syphilis or leprosy among the people. Microscopical examination showed a marked hyperplastic acanthosis, with an underlying round-celled infiltration of the perivascular connective tissues. The acanthous layer of the skin was thickened and prolonged in strands or columns. There were islands of connective tissue representing blood-vessels, surrounded by small round cells and plasma cells. The small-celled infiltration was most marked in the submalpighian connective tissue. The layers of skin were not distorted. There were no giant cells, tubercle bacilli, lepra bacilli, or cell inclusions. Normally yaws do not ulcerate, but they may break down and form ulcerations that last for years.

The Recognition and Treatment of Chronic Myocardial Disease.—A. A. Stevens regards fatty degeneration and fibroid induration of the heart muscle as the most important chronic affections of the heart wall. Both may be due to stenosis of the coronary arteries from atheroma, while fatty degeneration may also result from acute infections, cachectic states, and mineral poisoning. In fibroid induration there is a diffuse or circumscribed overgrowth of fibrous tissue in the heart wall. The circumscribed form results from the occlusion of an artery, forming an area of anæmic necrosis, and gradually replaced by fibrous tissue. The diffuse form is more common and results from a slowly developing endarteritis. Fibrous myocarditis may be secondary to chronic endocarditis or pericarditis; it may also result from the action of the poison of rheumatism, gout, syphilis, or alcohol circulating in the blood. Fatty and fibroid changes are often combined in the same heart. The symptoms may come on suddenly or insidiously. Slight dyspnœa on exertion, and paroxysms of cardiac asthma, or angina pectoris are the chief ones. Others are precordial uneasiness and hyperæsthesia of the neck, breast, axilla, and inner side of the left arm, progressive pallor and weakness, and attacks of syncope associated with indigestion. The pulse may become irregular or intermittent, and tachycardia and bradycardia are common. There may be no change on percussion, or there may be dilatation; the common auscultatory changes are feeble apex sound, and accentuated aortic second sound. The treatment consists in regulating the patient's muscular exertion, so as not to overtax the heart—in some cases the Nauheim treatment and adapting the diet to the digestive powers, somewhat restricting the amount of liquids taken, and forbidding tea, coffee, alcohol, and tobacco. The bowels must be carefully regulated. Strychnine is the most generally useful drug, $\frac{1}{60}$ to $\frac{1}{30}$ gr. three times a day. Arsenic is also very useful in small doses, for long periods. In robust men, with high arterial tension and anginoid pains, the nitrites and iodides are useful. Digitalis should be used with care, and strophanthus is to be preferred.

The Lancet, July 30, 1904.

The Red-light Treatment of Smallpox.—T. F. Ricketts and J. B. Byles think it worth while to publish their results to justify the apparent neglect of a remedy reputed to be of so much value. Their experiences were limited to but thirteen cases, but because their results were convincing of the inefficaciousness of the treatment, they did not feel justified in proceeding further with the treatment. They could not agree that the treatment had any of the merits which have been claimed for it. In their paper they believed that they had succeeded in showing not only that the case for this method of treatment was not proved, but that no serious evidence has been advanced in favor of it. It is their hope that the paper may have the effect of discouraging further application of the remedy, and they ventured to appeal to Dr. Finsen, who recommended this treatment some twelve years ago, and who had done so much for suffering humanity, to cease to lend the weight of his authority to support a method of treatment which, if it is inefficacious, must necessarily be inhumane.

Sleeping Sickness.—Aubrey D. P. Hodges says that sleeping sickness has been known in West Africa since 1803, but it did not become known to Europeans until 1900. One of the greatest difficulties in the study of this disease has been the extraordinary duration of the incubation period, from one to two, and even seven, years elapsing sometimes before the disease manifested itself. The disease attacks all ages and both sexes, although infants usually escape. Clinically and for convenience sake, the disease has been divided into three stages, the early stage, the pronounced stage, and the lethargic or somnolent stage. The earliest subjective symptom is a chronic or intermittent headache with lassitude and vague pains. There is a general enlargement of the lymphatic glands. One of the earliest signs noted is an arrhythmical, jerky, or twitching tremor of the tongue. Such symptoms occurring in a person who has visited an infected area is very suspicious. In the second stage the diagnosis is readily made, and dates from the characteristic facial expression and general appearance and changes in manners, habits, or disposition. This stage is not infrequently ushered in by nervous crises. The twitching of the tongue becomes more marked and the tremor spreads. The vague pains become more severe. At length the patients gradually pass into the lethargic stage. In surveying the symptoms broadly, two facts stand out fairly clear; first, they are to a great extent intermittent in character and not steadily progressive; and, secondly, on the whole the nervous symptoms are secondary to the general, a fact which points to a general infection, rather than a local disease. The two organisms which are at present being studied are the diplostreptococcus and the trypanosome; the latter occurs not only in the blood, but in the cerebrospinal fluid. The hypothesis of trypanosome causation seem to cover more of the facts. The reasons why there is a marked relative immunity for Europeans are probably: (1) Their manner of clothing leaves exposed a less area of skin than that of the natives, and only the more sensitive parts, the hands and the face. (2) They do not live, or lie asleep in the day-time, nor do they usually work in the jungle or forest.

British Medical Journal, August 4, 1904.

Some Results of Treatment by X-rays, High-frequency Currents, and Ultraviolet Rays.—J. Alfred Codd has grouped for treatment with high-frequency current myalgias and neuralgias of intractable or specially severe nature. The usual result is that pain completely leaves the patient at the first sitting, and he can move without difficulty. The pain returns after a time, but is less and of shorter duration after each treatment. In fifteen cases of refractory sciatica, lumbago, and facial neuralgia all were cured. Two cases of tinnitus aurium were much relieved. Two cases of nervous anorexia and vomiting were cured. Thirteen cases of lupus, rodent ulcer, and similar troubles have shown the marked superiority of the *x*-ray over excision and scraping. Some of these cases received ultraviolet rays at the same time with the *x*-rays.

Colitis Polyposa.—Frank Pope reports a case which presented a rare and unique condition. The symptoms consisted of pain in the abdomen for one hour and a half after food, with vomiting, bowels alternating between constipation and diarrhœa, and blood in the stools. She gradually failed and died from asthenia. The autopsy showed the walls of the colon thickened, the mucous membrane covered with pyramidal, polypoid excrescences, from the size of a shot to a pea; no ulceration; the growths were most frequent in the transverse colon, and extended into the rectum, where they were smaller. There were no secondary growths, but the lymphatics along the lumbar vertebræ were enlarged. The mucosa and submucosa were thickly infiltrated with small round cells; there were obstruction and dilatation of the gland follicles into small cysts filled with blackish fluid. It seemed to be the result of chronic inflammation rather than malignant. The author considers that this condition of hypertrophy was of slow growth.

The Present Position of Radium in Therapeutics; with a Summary of the Finsen Light and X-ray Treatment.—C. M O'Brien believes that in most cases in which these measures are indicated the Finsen light and *x*-rays should be

used in combination. He describes two cases of lupus in which radium has been used. The first had been under various treatments for thirty years for extensive lupus of the face. The application was made by means of 5 mg. of radium bromide in a vulcanite capsule; this was applied twenty times, for ten minutes at a sitting, during about three weeks. Nothing was noticed for a period of five weeks, when the edges of the patch became swollen and red, and the patient complained of stiffness of the muscles. Three weeks later the patch had assumed the appearance of a healthy scar. The second case had suffered from lupus for seven years. In about three months sixty-one applications were made. A week after treatment ceased the base of the ulcer was clean and healthy, with raised edges. The author believes that radium will not be of value in diagnosis. Lupus and rodent ulcer are benefited by the *x*-rays and the Finsen light.

Deutsche medizinische Wochenschrift, July 14, 1904.

The Diagnosis of Pathological Intoxication.—R. Kuttner calls attention to an abnormal condition of the muscle tonus and tendon reflexes in pathological intoxication which he claims differs from that found in the ordinary types of acute alcoholism. He reports five cases afflicted with transitory disturbances of consciousness, three of these suffered from typical epileptic attacks, the fourth presented symptoms which could be traced to epileptic degeneration, and the fifth phenomena which were due to the latter or to simple psychopathic weakness. A hereditary alcoholic history was present in three cases, the other two were doubtful. The points to which he calls attention are the delayed reaction to light in the pupils and the weakened muscles with absence or inhibition of the tendon reflexes. This is contrary to the conditions found in ordinary attacks of acute alcoholism.

Primary Diphtheria of the Renal Pelvis.—F. Krause reports a case in which this condition was cured by operative interference. The patient complained of pain in the region of the right kidney soon after a confinement. This grew worse and several months later was determined to be due to a pyelitis. Immediate operation was done, and on opening the pelvis of the kidney, the interior was found to be coated with a false membrane and filled with a necrotic mass. The kidney was then split open lengthwise and fastened in the wound with gauze strips after the manner already proposed by this author for suppurative processes of the kidney or its pelvis. The patient went into collapse after the operation, but eventually made a good recovery with complete return of the renal function. The microscopical examination showed the presence of a true pseudomembrane of the pelvis and a multiple acute interstitial nephritis. Gram's test was negative. The author claims to have been able to exclude all other methods of infection, and believes that the invasion was primary in this locality.

Constituents of the Blood Which Are Visible by Ultramicroscopic Methods.—E. Raehlmann examined fresh secretions derived from diseased mucous membranes, by means of the ultramicroscope recently devised, and found, aside from the emigrated white cells, numerous submicroscopic bodies derived from the epithelium and consisting of bits of protoplasm and nuclei. These gave evidences of mobility, both in shape and change of position. Further observations also showed that certain changes occurred in the blood plasma as well as in the cells, which may serve to explain the rôle which the blood-cells play in the metabolic processes of the organism. The detailed description of his findings will not bear abstracting. The conclusion reached by the author as the result of his observations is most interesting. It is well known that thousands of red blood-cells derived from the erythroblasts of the bone marrow, etc., enter the circulation constantly. The appearances revealed by the ultramicroscope lend color to the belief that the mature erythrocytes are broken up into most minute particles in order to make room for these accessions, and finally that the duty of these particles is to regulate metabolism within certain biological limits in every part of the body. The article contains a number of very convincing figures to illustrate the ultramicroscopic findings.

Diagnosis and Treatment of Azoöspermia.—Posner and Cohen comment on the failure of most methods for determining the presence of living spermatozoa where more or less obliteration of the seminal passages has taken place as a result of gonorrhœa. Fürbringer has proposed an operative measure by which the testicle is laid open and its contents examined. This is rather an extreme procedure, and in place of this the writers have employed puncture of the testicle by means of a hypodermic syringe. The advantages of such a procedure are painlessness, no necessity for an anæsthetic or confinement to bed. When the material thus secured is found to be free from spermatozoa, and consists of fatty cells and detritus, it is useless to attempt anything more. The question is what to do when spermatozoa are found. In six cases the authors have implanted the cut end of the vas deferens directly into the opened canals of the head of the epididymis, or have made an anastomosis by approximating and carefully suturing the edges of openings made in the wall of the vas and the epididymis. Thus far, however, no positive results have been obtained. The authors call attention to the necessity of instituting prophylactic measures by watching for the development of an epididymis after the acute stage of a gonorrhœa has subsided. If present, systematic massage, iodine applications; and other proven methods should at once be instituted. After the acute inflammation has disappeared, frequent examination as to the character of the spermatic fluid should also be made.

Deutsche medizinische Wochenschrift, July 21, 1904.

Rodent Ulcer.—P. Grawitz contends that there is only one epithelial form of rodent ulcer, and that those cases which have been described in literature as endothelioma of the skin have not been sufficiently traced as to their origin. He bases this statement on the study of a large series of sections in which he found that the successive stages of growth may be differentiated in serial sections, and that in this way all the forms may be demonstrated, including those which have recently been described by various authors as endotheliomata. The rodent ulcers, or as he designates them, the matrix carcinomata, may be divided into four parts: (1) the solid knobs with buds; (2) transition of the covering epithelium into the lymph spaces, which may be compared pictorially with icicles hanging from a roof; (3) a mixed proliferation dating from all the layers of the epidermis; and (4) the glandular type. All these may be found in the same small nodule. For a more complete understanding of the subject, it is necessary to consult the original paper.

The Marx-Ehrnrooth Method for Differentiating Human and Animal Blood.—H. Pfeiffer has made an extended trial of this method, which is based on the fact that the erythrocytes of one species (*a*) are agglutinated by the serum of a second, but not too closely related species (*b*), while homologous sera are not attended by this reaction. It was found that the agglutinating powers for different varieties of serum vary with respect to the human blood corpuscles. Also that in many cases in which the agglutination can be demonstrated with certainty, on account of the extreme dilution of the serum, the diagnosis may be made on the corrugated forms and the hæmolysis. Beyond certain boundaries, moreover (1:512—1024), a definite distinction cannot be made, as the preparations made with these dilute heterologous sera can scarcely be differentiated from the controls. The latter fact is of great importance in forensic practice, as a negative result does not necessarily mean an identity of the two sera. The author claims that the method is simple in application and very valuable, and in most cases serves to distinguish with certainty the specific similarity or difference of any given albuminoid solutions. It is essential, however, that the suspected material be determined with absolute certainty to be blood.

Berliner klinische Wochenschrift, July 11, 1904.

Foreign Body in the Left Ventricle.—M. Koch reports an interesting instance in which, at the autopsy examination in a man of seventy-two who died from inanition, a needle-like body about 3 cm. long was found imbedded in the wall of the left ventricle. There was no clue as to the origin of the condition to be gained fom the patient's history. The author is inclined to believe that the object was introduced suddenly from without at some remote period in the patient's life, judging from the direction of the needle, its position in the cavity and wall of the ventricle with the end fixed in the septum, and the absence of any changes in the pericardium.

Diagnosis and Treatment of Tabes.—E. Coester calls attention to the necessity of making a diagnosis of this condition as early as possible, and claims that there are many symptoms which should lead to suspicion that may be present before the classical signs in pupils and the tendons come on. He describes a number of his own cases in which doubt existed, but the test of treatment was effectual. Vague pains in different parts of the body, which are often considered to be due to gout or rheumatism, and paræsthesiæ, should lead to more careful inquiry with especial reference to luetic infection. In the so-called incipent cases a thorough course of antisyphilitic treatment was always found to result in a cure of the symptoms.

Remarks on Adenoid Vegetations.—Lublinski states that although there is little new to be said on this subject, there are still a number of important points unsettled. Among them is the question as to whether these proliferations are to be considered, as evidence of a scrofulous affection. Such a diagnosis should be well con-

sidered, especially in the presence of enlarged cervical glands. Wherever the latter are present, however, a thorough examination of the nasopharynx should be made, for adenoid vegetations may be present without causing any mechanical disturbances, and there may be no relation between the size of the glands and the degree of adenoid hypertrophy. The same applies to affections f the ear, where even small proliferations may bring about chronic ear disease. The connection between follicular conjunctivitis and adenoids has been observed by a number of authors, and here also the proliferations need not be extensive to be the cause of the eye conditions. In some cases the only thing which attracts attention is the chronic coryza with which the child seems to be afflicted. Other conditions which the author attributes to the presence of adenoid vegetations are the irritating cough of many children, which he has found in most instances to be due to the strings of mucus dropping down from these growth in disturbances of digestion, also from this secretion and the reflex irritation which results in constant gagging and retching; impaired mental conditions, marked chiefly by inability to concentration of the attention on an object on any length of time. The writer is of the opinion that operation should always be undertaken whenever conditions warrant, and is inclined to believe that operative procedures are instituted in too few, rather than in too many instances.

Berliner klinische Wochenschrift, July 18, 1904.

Congenital Anomalies in the Coccygeal Region.—T. Brugsch calls attention to the congenital anomalies of development in this region, which are comparatively rare and seldom come under observation by the physician. He reports a case in which there was a marked depression at the level of the last sacral vertebra, lined with epithelium and about 2 cm. deep. The fundus was apparently attached to the tip of the coccyx by a band. The condition was unattended by symptoms, but in some instances the epithelial lining may be lacking and the presence of mucous membrane forms a fistula with resulting inflammation of the surrounding parts. This condition must be distinguished from that due to a spina bifida, which is to be found more craniad and in connection with other anomalies in development of the vertebræ. The author traces the condition noted to atavistic remnants of a caudal appendage.

Therapeutic Value of Dreyer's Method of Photography.—The latter is based on the belief that the injection into the tissues of a solution of erythrosin renders them more sensitive to the action of the red rays, and therefore permits of greater penetration of these agents. B. Spiethof reports the results of his clinical experience with six cases of lupus, three of which had been treated with the ordinary Finsen rays without having secured a complete cure: the remainder had not been thus treated. Attention is called to the fact that the reaction after exposure to the Finsen rays is much more intense when the injection has been given than without the same. Experiments made in animals showed that the one-per-cent. solution of erythrosin was followed by a marked reaction, but none was noticed with the use of a 0.25-per-cent. solution. The reaction is therefore a combination of two factors—the injected material and the rays. As for the clinical cases, the author's experiences were practically negative, and no better results were obtained with the injections than in those in which no injections were used. He does not feel sanguine about the practical value of the method.

Münchener medizinische Wochenschrift, July 12, 1904.

Optic Neuritis in Paratyphoid Fever.—G. Flatau reports the occurrence of a double optic neuritis in a young woman in whom the diagnosis of paratyphoid had been made by bacteriological tests. This complication has been reported a number of times in pure typhoid infection and was believed to be directly due to the influence of the typhoid toxin. In connection with paratyphoid it has not been observed, however, and is here noticed to again call attention to the identity as regards the clinical course between the two diseases.

Abortive Treatment of Acute Gonorrhœa.—Bettmann calls attention to the advantages which would attend such a plan of treatment, although the results thus far obtained have led most practitioners to regard any procedures of this kind with suspicion. As it is acknowledged that the gonococci penetrate the deeper epithelial layers very quickly, the author has endeavored to find a remedy which in addition to its bactericidal power would also bring about increased transudation and cause the cocci to come to the surface. He has had excellent results with a solution of protargol, in glycerin and water, in the following proportions: 10 gms. of protargol are dissolved in 45 c.c. of cold water, without shaking the vessel, and then enough glycerin added to make up 100 c.c. The best effects were obtained by applying the solution to the interior of the urethra with a specially devised hair-brush. This is done daily, or every second day, until from six to eight applications have been made. In forty-two cases treated, positive results were found in twenty, fifteen were negative, and seven doubtful. The best results were obtained in those instances in which the treatment was begun three days or less after infection had taken place. The procedure is attended with very little discomfort on the part of the patient. A mucopurulent secretion may be present for several days, but after that the gonococci disappeared. Even in those cases which he considers negative because the secretion containing the cocci persisted there were no complications, not even a posterior urethritis.

The Administration of Morphine in Cardiac Disease.—K. Grassmann presents an extended polemical discussion on this subject, the main points of which are as follows: He does not think that we are justified in asserting that morphine is a cardiac poison in therapeutic doses, and that for this reason its employment is to be avoided in such cases. The sudden deaths which sometimes occur in patients with cardiac disease to whom morphine has been given must be placed in the same category with those resulting from chloroform narcosis, in which cardiac paralysis takes place. The reason for either remains still unexplained. The authorities vary greatly in their opinions as to the proper indications for the administration of morphine in cardiac disease, and it would be desirable to formulate more precise indications which are based on observations made on a large amount of clinical material. Where there is cardiac weakness or disease accompanied by disturbances of the respiratory organs, especially of an acute character, or where acute processes of the endo- or myocardium are present, the drug must be given with caution. In the case of pure neurotic disturbances, particularly in angina pectoris due to non-organic causes, morphine may be given without fear. It may also be administered in stenocardia and is indicated without restriction in the severer form of cardiac asthma. Another indication for the use of morphine is in those cases in which digitalis and similar drugs are inefficient or no longer produce any effect. The most important use of morphine is as a preparatory remedy (which may be compared to its injection before anæsthesia) before digitalis administration, in cases marked by restlessness and sleeplessness. This condition serves as a direct indication.

Münchener medizinische Wochenschrift, July 19, 1904.

Iodine Catgut.—H. Fuchs considers that this form of sterilized catgut is the best thus far introduced, as it is simply and easily produced and very effective. It may be depended upon to be free from germs, and its antiseptic properties counteract to a certain extent any possible contamination resulting from handling. The iodine does not produce any irritation when left as buried sutures, and does not interfere with absorption. Iodine catgut is very tough, and therefore especially well adapted for ligatures. The author does not recommend it, however, for skin sutures, as it seems to cause considerable irritation in the skin.

Prophylaxis of Yellow Fever.—E. V. Bessawitz presents certain suggestions for the prophylaxis against this disease which are based on Finley's theory of its communicability. It devolves upon the Government to destroy the breeding places of mosquitos which are to-day recognized as at least one of the intermediate hosts of the specific disease-producing factors, and also to isolate and protect the patients. In addition, it is also necessary for the individual to protect himself against the bites of these insects with proper netting, and to kill them in his dwellings. Netting is good, but not sufficient. The author has found that the ordinary insect powder (Flor. pyreth.) when rubbed into the skin was most effective in driving the insects away. He suggests that the active principles of the remedy be isolated, so that they may be incorporated in other powders or ointments which may be made to adhere better to the skin. Salves, however, are not suitable to the tropics, and better results may be obtained if the essential oils of this powder could be isolated and employed.

The Disposition of Ingested Foreign Bodies.—Appel reports an interesting case of a man of sixty-two years who was suddenly seized with an acute pain in the left inguinal region, which recurred during the next few days. The tender swelling was believed to be a hernia. The pain always subsided on lying down, but came on with great severity when standing. The "hernia" could not be reduced, but no intestinal symptoms were present. At the operation no complete hernia was found, but in the canal was a portion of the properitoneal fat, containing a bit of bone about 2 cm. long, about half of which projected into the free peritoneal cavity. The bone was extracted and the man made an uninterrupted recovery. There was nothing in the patient's history to afford any

clue as to when the bone was swallowed, and it probably entered without having caused any immediate symptoms. The author explains its arrest at this particular point, by assuming that there was a protrusion of the peritoneum at the internal inguinal ring, in which a coil of small intestine became adherent. This constituted a partial obstruction in which the bit of bone was caught and finally driven through the wall of the gut. The closure resulted in the same manner as is known to occur with other perforating wounds of the intestine by bullets or pointed instruments.

French and Italian Journals.

Hemiplegia Due to Lumbricoid Worms.—A. Sigaud was called to attend a child of six years. While the patient was eating his supper, his eyes became fixed and he fell as if in a fit. His head, although turning either to the left or to the right, remained by preference turned to the left, and the eyes were rolled up and deviated to the left, with dilated pupils. The child did not speak, but only mumbled. The right arm and leg were paralyzed. The child made a movement of contraction if it was pinched, but if it was raised, it tumbled back inert. Calomel and santonine were administered and the child passed twenty worms. Soon after it began to improve; it spoke, asked to eat; the paralysis diminished, and in five days it had entirely recovered.—*Gazette des Hôpitaux Civils et Militaires*, June 30, 1904.

On Some Special Eosinophile Formations Simulating the Bodies of Negri, in the Cells of the Cerebrospinal Ganglia of Hydrophobic Men.—Pace has examined the cerebrospinal ganglia of four cases of hydrophobia in the human subject. He has demonstrated, by the method of Mann, in the cells of the cerebrospinal ganglia, the cornu Ammonis, and the ganglia of the vagus, special formations, differing in size and shape, occurring as fine granules, corpuscles, and morula forms. The last consist of four to five small bodies fused together, or arranged around a central body, as in a rosette or mulberry, without any capsule or membrane. He suggests that these forms may be the sporulation forms of the corpuscles of Negri.—*La Riforma Medica*, June 22, 1904.

Metastatic Cancer of the Choroid.—Bailliart reports this interesting case. The patient was a woman of fifty-eight years, who for three years had had an ulcerated cancer of the right breast. In September of 1903 she began to be troubled with digestive disturbances. The treatment, lacto-vegetarian régime and purgatives, did not result in any improvement. In the first days of October the patient noted a distinct diminution in the clearness of vision in the left eye. The trouble increased slowly but constantly. Pain was slight. Two months later, paralytic disturbances developed—of the right leg and arm. The physician consulted, advised an ophthalmoscopic examination. Double myosis was noted. At the lower part of the retina a swelling was seen. Diagnosis of metastatic cancer of the choroid was made, and the paralytic symptoms were explained by the supposition that there was another metastatic focus in the vertebræ. The pain so slight at first, increased, but enucleation was not proposed on account of the cachectic condition of the patient. Other metastases occurred later, and death supervened in January, 1904. There was no autopsy.—*Recueil d'Ophthalmologie*, June, 1904.

Foreign Bodies in the Ear.—H. Grandjean calls attention to two cases which have come under his care. The first patient was a girl of eighteen who was suddenly attacked with complete deafness of the left ear. She had always heard well before. There was neither local swelling nor irritation. On examination with the speculum, the writer found the end of the canal filled with a mass of wax. The extraction by means of a syringe was accomplished with difficulty. The wax fell into the basin with a thud. It was found that a bead was in the mass. It was then remembered that fourteen years before, the girl had pushed this bead into her ear. It had given no trouble till this time. The second patient consulted the writer for and otorrhœa which had troubled him for fifteen years and from which he had never been able to obtain relief. The writer succeeded in dislodging a fragment which a playmate had thrust into the ear fifteen years before. It had caused a purulent otitis with destruction of the tympanum. After three weeks of treatment, the otorrhœa had almost completely disappeared and the patient was lost sight of. The writer advocates the use of hydrogen peroxide in the auditory canal in extracting wax or foreign bodies that are hard to dislodge.—*Revue Médicale de la Suisse Romande*, June 20, 1904.

Gaseous Gangrene in the Course of Typhoid Fever.—E. Gruet reports a case of Schmerer's of this nature. The patient, aged twenty-two years, had just passed two months in prison under the most unhappy conditions, when he was obliged to walk about 120 kilometers in five days. At the end of the route his strength was exhausted and he entered the hospital. He was found to be suffering with typhoid fever at about the twelfth day. He suffered with headache, insomnia, great lassitude, and diarrhœa, which had been preceded by constipation. An ecchymotic area as large as the palm of the hand was noted above the left knee. In two days, the patient suddenly complained of extreme pain in the left knee, which quickly swelled. Delirium, coma, asphyxia, and death followed. Autopsy disclosed deep ulcerations of Peyer's patches, gas in the femoral veins and their different branches up to the heart, in whose interior were black clots with fluid blood mixed with gas bubbles. The liver showed under its capsule fine bubbles of gas. The left knee was distended with fluid blood mixed with gas. Microscopical examination of the blood showed a considerable number of motile bacilli, some of them isolated, and some in short chains. The species was not determined, as the necessary culture media were not at hand. The lesions were identical with those observed in animals which have died of gaseous gangrene.—*Le Caducée*, July 2, 1904.

The Manifestations of Hereditary Syphilis in Earliest Infancy.—Ludovico Fini states that infants, subjects of hereditary syphilis, are born pale and ill-nourished, with dry and wrinkled skin; that they generally breathe badly from rhinitis and nurse poorly for the same reason. Some are born with the skin lesions, while in others the skin becomes affected soon after birth. Kossowitz found that in 124 cases observed the skin lesions came on during the first month of life in 66 cases; in the second month in 40 cases; in the third month in 18 cases. The manifestations of the disease may be found in all the organs and tissues. The skin eruptions are erythematous, papular, or bullous, most frequently the last. The common seat of the erythema is the neck, face, sides of the abdomen, palms of the hands and feet; this forms a point of differential diagnosis from simple erythema, which is about the anus and buttocks in ill-nourished children. The papules of syphilis may ulcerate and form deep ulcers, with grayish base. They occur on the trunk, neck, arms, and at points of irritation. The bullous form is commoner. The commonest manifestation is the so-called syphilitic pemphigus occurring on the hands. The bones are frequently attacked, especially at the junction of the epiphyses of the long bones. The pseudo-paralysis of Porro arises from the pain resulting from movement of the softened bones. Hydrocephalus is not rare. Changes in the teeth are not as common as at the second dentition, when the true Hutchinson's teeth appear. Iritis, iridochoroiditis, and interstitial keratitis are not rare. Of the internal organs, the spleen and liver are usually enlarged.—*Gazzetta Medica di Roma*, June 1, 1904.

Ankylosis of the Vertebral Column with Especial Reference to Spondylosis Rhizomelica.—Pietro Fiorentini considers the subject of vertebral ankylosis in general, and reports a case of spondylosis rhizomelica which came under his observation. Ankylosis may be complete, with fibrous union of the articular surfaces, changes in the articular surfaces, and degeneration of the muscles. It may be incomplete, with cellulofibrous union. Or it may be incomplete, with loose union. The principle causes of ankylosis of the spine are as follows: All forms of chronic spinal meningitis, especially hypertrophic cervical pachymeningitis; if of syphilitic origin, we may have hyperostosis, caries, or arthritis; Pott's disease also produces anyklosis; blenorrhagic infection may produce it; it occurs in Paget's disease; in acromegaly; in syringomyelia; in spinal rheumatism of the ordinary type, and in spondylosis rhizomelica. The last mentioned disease is of rare occurrence. It has been reported by Strümpell and by Marie and Bechterew under slightly different types. It is an affection in which there is a gradual and sometimes painless ankylosis of the vertebræ and of the articulations of the hips, while the other large articulations remain free. According to some, it is of true, rheumatic origin, while others believe it to be the result of traumatism or hereditary neuropathy. In the author's case there was first pain in the left knee with limitation of motion, then the same symptoms in the hip, lumbar region, and coccyx; rigidity of the entire spine coming on in a relatively short time, with slight limitation of the motion of the right lower extremity. The pathogenic agent was plainly rheumatism, which may have been aggravated by an attack of influenza. The trouble in the limbs began at the age of sixteen years, while at the time of the report the patient was thirty-two years old. It differed from simple rheumatism in that the articular trouble was confined to the spine and large adjacent joints. The author believes that spondylosis rhizomelica is not a variety of true rheumatism, but originates from trophic disturbances, of diathetic origin, and is probably toxo-infective.—*Rivista Critica di Clinica Medica*, July 2-9, 1904.

Book Reviews.

THE OPHTHALMIC YEAR-BOOK. A Digest of the Literature of Ophthalmology, with Index of Publication for the Year 1903. By EDWARD JACKSON, A.M., M.D., Emeritus Professor of Diseases of the Eye in the Philadelphia Polyclinic; President of the American Academy of Ophthalmology and Oto-laryngology; Ophthalmologist to the Denver County Hospital, St. Anthony's Hospital and Mercy Hospital, Denver, etc. Denver: The Herrick Book and Stationery Company, 1904.

THOSE who are interested, either theoretically or practically, in eye work are in all truth under great obligations to Dr. Jackson for his very compact and attractive Year-book. It contains several hundred pages and is a digest of abstracted articles covering the main original communications dealing with ophthalmology during the past year. As the author states in his announcement, it is not an easy task to cull the best out of the twenty or thirty thousand pages of ophthalmic literature, as presented to the profession each year, and yet he has given us much that is of real merit and practical worth for both the general practitioner and the specialist. For those wishing to get at a complete list of the recent writings on ophthalmology, his accurate alphabetical index of authors and their works, whether books, monographs, or journal articles, is indispensable and a saver of time and labor.

The Year-book has a well-arranged table of contents and a full index. It behooves those who are interested in this branch of medical science, and who wish to keep up with its advances, to have at their disposal this little book of reference.

ELECTRODIAGNOSIS AND ELECTROTHERAPEUTICS. By Dr. TOBY COHN, Nerve Specialist of Berlin. Translated from the Second German Edition and Edited by FRANCIS A. SCRATCHLEY, M.D., of New York. With eight plates and thirty-nine illustrations. New York and London: Funk & Wagnalls Company, 1904

As between those who make extravagant claims for the diagnostic and therapeutic utility of electricity and those who attribute principally to suggestion such effects as appear to result from the employment of this agent, the general practitioner has no little difficulty in reaching a decision in the matter. It is admitted by conservative electrotherapeutists that under many conditions electricity does exert a profound suggestive influence, but over and above this, it is capable of certain physical, chemical, and physiological effects that may be usefully directed to the treatment of the various morbid conditions. Electricity as a therapeutic agent does not differ thus essentially from other therapeutic agents, and accordingly, in order to obtain the best results from its employment, due consideration must be given to its indications and counter-indications, its dosage, and its mode of application. Likewise a knowledge of its source or method of generation, of its qualities and effects, will contribute to its more intelligent use. These several factors are given consideration in the work before us, which is divided into two parts, namely: I. Electrodiagnosis and II, Electrotherapeutics. Six chapters are devoted to the former and five to the latter, and there is an Appendix dealing with the newer applications of electricity, such as magnetic electrical treatment, the sinusoidal current, the undulating current, the Jodko current, condenser discharges, and magnetic treatment with the alternating current.

PRÉCIS DES MALADIES DES ENFANTS. Par le Dr. L. BAUMEL, Professeur de Clinique des Maladies des Enfants à l'Université de Montpellier, Médecin en chef a l'Hôpital Suburbain. Paris: F. R. de Rudeval, 1904.

THE author divides this book into two general parts, which are again divided into sections or chapters. In the first part he deals with general affections, such as rickets, scurvy, anæmia, chlorosis, diabetes, cretinism, malaria, typhoid fever, syphilis, and the exanthemata. In the second part, special diseases are discussed—diseases of the skin, of the eye and ear, of the digestive, respiratory, and genitourinary apparatus, of the heart and liver, and of the nervous system. The general treatment of subjects is much like that found in the ordinary book on Practice; the definition, etiology, symptoms, complications, diagnosis, prognosis, and treatment of the various diseases being considered The volume is a veritable résumé of Pediatrics. The author calls attention to the fact that the majority of physicians, if not all, are obliged at times to care for sick children. This volume will prove of great value to the general practitioner as well as to those especially interested in children's diseases.

STUDIES FROM THE DEPARTMENT OF NEUROLOGY of Cornell University Medical College. Vol. I. New York, 1904.

THE series of publications of the Cornell Medical School is inaugurated by this volume of studies from Prof. Charles L. Dana's department of neurology. The volume contains nineteen papers on the clinical and pathological studies completed in the department during the year, seven of which are published here for the first time, the others being in the form of reprints from various medical journals. The authors of the papers are Drs. C. L. Dana, J. Ramsay Hunt, Joseph Fraenkel, and F. W. Hastings. Apart from the scientific merit of the several articles, the volume is interesting by reason of the epitome, written in Latin, which precedes each paper. It is pleasing to the reader, several decades out of college, to find that (knowing previously what the article is about) he can understand the epitome. Perhaps another, less remote from his Juvenal and his Livy, might grasp the sense of the epitome without a previous acquaintance with the article in English. It is an interesting experiment, however, and any educated foreigner, ignorant of English, would doubtless, with little difficulty, be able to inform himself of the value of the article and determine whether the subject was of sufficient interest to him to make it worth his while to have it translated. The plan is one that might profitably be adopted generally in scientific publications.

A COMPENDIUM OF CHEMISTRY, INCLUDING GENERAL, INORGANIC, AND ORGANIC CHEMISTRY. By Dr. CARL ARNOLD, Professor of Chemistry in the Royal Veterinary School of Hanover. Authorized Translation from the Eleventh Enlarged and Revised German Edition. By JOHN A. MANDEL, Sc.D., Professor of Chemistry, Physics, and Physiological Chemistry in the University and Bellevue Hospital Medical College. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1904.

AMONG German students Arnold's "Repetitorium der Chemie" has for two decades or more held its place as the most popular of all chemical textbooks, and that it is now accessible to English-speaking students of chemistry is a cause for congratulation. The work has been issued in new editions about every second year, and it is from the eleventh German edition that this translation is made. This, the latest edition, "contains concise but clear statements of the most important theories and facts, especially in the recently developed domain of physical chemistry, as well as a classified review of the most important inorganic and organic compounds, including statements of the constitution and derivation of these substances." An index of over fifty pages, so unusual a feature in a German book that we suspect Dr. Mandel is guilty of its perpetration, adds greatly to the value of the book as a work of reference. The difficult task of translating a German scientific work has been so well done as to call for special comment.

CLINICAL TREATISES ON THE PATHOLOGY AND THERAPY OF DISORDERS OF METABOLISM AND NUTRITION. By Dr. CARL VON NOORDEN. Translated by BOARDMAN REED, M.D. Part V. Concerning the effects of Saline Waters (Kissingen, Homburg) on Metabolism. New York: E. B. Treat & Co., 1904.

THIS monograph of von Noorden contains a great many practical points of much value, especially with regard to the therapeutic use of saline waters. According to this clinician, the following points deserve attention:

1. In numerous cases of gastric disorder, particularly in gastric catarrh, the use of saline mineral waters leads to an active and permanent increase in the production of hydrochloric acid.

2. In numerous cases of gastric disorder accompanied by hyperacidity (particularly in nervous dyspepsia) the moderate use of saline mineral waters leads to a decrease of the hydrochloric acid production and a decrease of the subjective symptoms.

3. The administration of saline mineral waters does not call for any particular diet. To adhere to such dietetic schemes as the ones arranged in the different watering places is an antiquated procedure, and one that must be considered a dogmatic method of treatment that may be deleterious to the patient. There is above all no reason why large quantities of fat should not be given in suitable cases to patients who are drinking certain mineral waters. Nor is there any urgent reason for forbidding the use of raw fruits, vinegar, salads, etc., in specified cases.

4. The ingestion of large quantities of saline mineral waters does not interfere with the absorption of the food; in particular, the absorption of the fats; this is demonstrated by numerous investigations on patients.

5. The metabolism of the proteids is not increased by saline mineral waters, so that these waters can be employed even in those cases in which it is important to maintain the albumin content of the body—that is, in patients undergoing a reduction cure.

6. The excretion of uric acid is slightly increased when dilute saline mineral waters are taken. This increase in the uric-acid excretion is sufficiently marked to justify the use of such waters in the treatment of uric-acid retention.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventy-second Annual Meeting, Held at Oxford, July 26, 27, 28, and 29, 1904.

(Special Report to the MEDICAL RECORD.)

THE seventy-second annual meeting of the British Medical Association was held at Oxford the last week in July, beginning on Tuesday. At 10.30 in the morning of that day there was a special service in the Cathedral, Christ Church, the large building being crowded. Rev. Dr. Franck Bright, Master of University College, preached the sermon from John v. 17: "My father worketh hitherto and I work." At the same hour mass was celebrated in the Catholic Church of St. Aloysius.

GENERAL SESSIONS.

First Day—Tuesday, July 26.

The meeting was held at noon, in the Examination Schools, the retiring president, Dr. Thomas Dryslwyn Griffiths of Swansea, occupying the chair, and about 600 delegates were present.

Address of the Retiring President.—Dr. THOMAS D. GRIFFITH of Swansea, in his address, first referred to the death of Sir John Simon, the pioneer of modern sanitary science. They revered his name and they owed a great debt of gratitude to his memory for the services he had rendered to the profession and the incalculable benefit he had conferred on the community and, indeed, on the whole civilized world. They might safely say that Sir John Simon saved far more lives during the last fifty years than all the armies of the world had destroyed during the same period. He did for sanitation what Lord Lister had done for surgery and what Pasteur had done for bacteriology.

They had now come to the close of the first year of the new constitution, and it was very gratifying to find that it was fully realizing their anticipations. The changes and alterations were now practically complete. The divisions were all arranged, the boundaries were fixed, and they had their own rules and regulations, which had been sanctioned by the Central Council. One great advantage of the new constitution was the formation of divisions which were well calculated to answer the purpose of local medical societies, and, in addition, to form part of the British Medical Association. A great many of those local societies were being amalgamated with the divisions and for the sake of economy, convenience, and policy. These divisions, which were about 300 in number, covered the whole of the United Kingdom and most of the colonies.

One other great advantage gained by a reconstruction was the additional power to promote the interests of the profession, greater power to improve public health and the well-being of the community, greater power to guide and influence Parliament in legislating for the health of the people.

It was his belief that the association could not fail, under a new democratic organization, to enlist, within a very few years, the sympathy and the active coöperation of all the qualified medical men in the British Empire, a consummation devoutly to be wished. He felt he would fail in his duty if he were to have the chair without referring to the kindness which he had received during his year of office. He wished to offer his best thanks to Mr. Andrew Clark, Chairman of the Council, to Dr. Dawson Williams, the able editor of the association journal, to Mr. Guy Elliston, the General Secretary, and to Dr. Whitehead, Medical Secretary, for their courtesy and the invariable kindness and assistance they had given him. The first duty he had had to perform as their president was one of very great pleasure to him and one he considered a great honor as a native of the principality. It was to propose his Royal Highness, the Prince of Wales, as an honorary member of the association. His Royal Highness, like His Majesty, the King, a patron of the British Medical Association had always shown very great interest in all questions relating to public health and the well-being of the community.

The speaker's last duty was also one which gave him great pleasure, and this was to introduce Dr. Collier to them. Dr. Collier might not be known to some of them, but the speaker was sure he was well known to them as an able and accomplished physician, and as a lecturer in the medical school of this great university whose hospitality they were then enjoying. Dr. Collier had, without any influence except his own ability, perseverance, and force of character, advanced at a very early age to the first rank of the profession, a position which older men might envy.

Induction of the New President.—Dr. WILLIAM COLLIER then took the chair amid applause. He said he would like, first of all, to thank the members very heartily indeed for the very great honor they had done him in putting him into the position of President of the Association. He thoroughly realized the honor, and his only hope was that he should be able in some degree to prove worthy of it. He knew quite well how valuable their time was, and he would only ask them to allow him to trespass for a very few minutes on it. There was one thing he wished to do. He wished first to disarm criticism and to elicit their sympathy. When the Oxford Division ventured to invite the Association to meet at Oxford they had not the faintest conception that Oxford would prove such a very pleasant and popular rendezvous. They also had no idea that so many wives and daughters would absolutely refuse to allow their husbands to come to Oxford unaccompanied by themselves. They were very soon agreeably undeceived, because a week or two ago when the names began to come in they found in the first 200 that no less than twenty-one gentlemen signified their intention of making altogether eighty-six visitors. They saw that would be absolutely overwhelming, and so they were compelled to put all kinds of stop notices in the *British Medical Journal*. He hoped they would not for one moment take this as an indication of their want of hospitality. They realized quite well that they could not increase their college gardens, and that they could not put up new buildings, and therefore that it was absolutely necessary to warn them in the way they had done. They also recognized this fact, that it was one of the characteristics of the British nation when they met together in crowds to be cheerful and good-natured, and it was one of the most characteristic things of the medical profession that they were perfectly prepared to be cheerful and to put up with certain discomforts. He was sure they would live up to that reputation. For weeks past their executive, and especially their secretaries, had been talking and thinking and dreaming of nothing but how to make the meeting a great success. They certainly hoped they would be able to do so.

Dr. GALTON of Norwood then moved a vote of thanks to Dr. Griffiths, the retiring president, for his very able conduct in the chair during the past twelve months, and, in accordance with By-law 36 that he be elected a vice-president of the Association for life. The motion was seconded by Mr. Morris of Portmadoc, and unanimously carried.

The President then proposed that the Vice-Chancellor of the University, Dr D. B. Monro, the Dean of Christ Church, the Very Rev. T. B. Strong, and the Master of University College, Dr. Bright, be elected honorary members of the Association, for their valuable services rendered in connection with the Oxford meeting. The Oxford Division was a small one, and when a question of issuing the invitation came up they felt they could not feasibly do it without some begging from the University, but they had had no idea that the University would behave in such an extraordinarily generous manner. He had never asked the University to do anything for them which had been refused, and he thought that was saying a great deal. When they looked at those magnificent schools he thought

they would say it was very generous of them to allow the Association to hold its meetings there. It was a very happy thing that they were enabled to name these three gentlemen, because two of them were associated with the medical profession in a very close and peculiar fashion. The Vice-Chancellor was the grandson of the third Monro of the family of Monros who founded the great medical school at Edinburgh, while Dr. Bright was the son of that Dr. Bright whom they all so well knew as the great physician of Guy's Hospital.

The proposition was unanimously adopted.

Sir Victor Horsley then moved that Professor A. G. V. Harcourt, M.A., F.R.S., be elected an honorary member of the Association for the valuable services he had rendered to the Association through the Special Chloroform Committee. He said it was one of the privileges the Association owed to the University that three years ago the then Lee's Reader in chemistry at Christ Church came forward with his valuable assistance in the matter of chloroform research. What Mr. Harcourt had done for the Association could not be said in a few moments, and he would therefore simply content himself with moving the resolution in order that the Association might in some sense express its gratitude to Professor Harcourt

Dr. Skerritt seconded, and the resolution was heartily adopted

Evening Meeting.—In the evening the Sheldonian Theater was crowded, The Vice-Chancellor, Dr. Monro, presiding. The meeting was held for the purpose of receiving a large number of distinguished foreign and colonial guests, and for the delivery of the presidential address.

Addresses of Welcome.—The Vice-Chancellor, on behalf of the University, gave a hearty welcome to the Association, remarking that the meeting was what their young friends would call a "record" in point of attendance, and evidently the interest taken in these meetings was greater than ever.

The Mayor, Mr. E. A. Bevers, on behalf of the city, also gave a cordial welcome to the Association, and said the corporation had paid the greatest compliment in its power to the medical profession by appointing one of its members to the mayoralty on the occasion of the visit of the Association.

The President, on behalf of the Oxford Division, also extended a warm welcome to the Association and to the distinguished foreign guests and colonial delegates. He wished particularly to call their attention to the pathological exhibit which had been provided. So good was it that he quite expected many of his hearers would cut off a few days of their holiday for the purpose of staying a while to examine it at greater leisure.

The various foreign and colonial guests were then presented to the President by Dr. Drew, who also presented to Dr. Collier, on behalf of the executive committee, the official badge of the Association.

The Middlemore Prize.—The President announced that the adjudicators had awarded the Middlemore Prize of a certificate and a check for £50 for the best original work on ophthalmology brought out during the past three years to Mr. John Herbert Parsons, M.B., B.S., D.Sc., F.R.C.S., of University College Hospital, London.

The Presidential Address was then delivered by Dr. William Collier (see p. 223). He was most cordially received on rising, and at the close of the address received a vote of thanks, as did also the Vice-Chancellor for presiding.

Second Day—Wednesday, July 27.

This morning services were held in the chapels of Mansfield College and Manchester College at nine o'clock, and sittings of the various scientific sections took place in the University Museum from ten to one o'clock.

Conferment of Honorary Degrees.—A convocation was held at two o'clock in the Sheldonian Theater for the purpose of conferring the degree of Doctor of Science, *honoris causa*, upon the following: Dr. T. C. Allbutt, F.R.S., Regius Professor of Physic at Cambridge; Mr. Andrew Clark, F.R.C.S., Vice-President and Chairman of the Council of the British Medical Association; Dr. T. D. Griffiths, late President of the Association; Mr. Jonathan Hutchinson, F.R.S., late President of the Royal College of Surgeons; Sir Wm. Macewen, F.R.S., Regius Professor of Surgery in Glasgow University; Sir Patrick Manson, K.C., M.G., F.R.S.; Sir John W. Moore, late President of the Royal College of Physicians of Ireland; Dr. Wm. Osler, F.R.S., Professor of Medicine at Johns Hopkins University, Baltimore. Owing to the illness of a near relative, Dr. T. G. Roddick, M.P., of Canada, on whom it was also intended to confer the degree, was unable to be present.

The recipients of the degree were presented by Professor Love. In introducing Dr. Allbutt he said the work to which his name would always be associated was the treatise on medicine for which he had enlisted the assistance of so many of the physicians and surgeons in the United Kingdom. Mr. Andrew Clark was spoken of as having contributed notably to raising the medical profession in the public estimation, and he was a high officer among those who could be called upon to render medical service to the army in case of war. Dr. T. Dryslwyn Griffiths was referred to as one who had achieved great distinction as a physician, and as the author of numerous memoirs of great value relating to medical subjects, and in Wales especially he was looked up to as a leader of the profession. Mr. Hutchinson was introduced as a man who excelled not only in the practice of operative surgery, but also in the investigation of the causes and in the treatment of those diseases of which the surgeon was the true healer. In particular he had made a special study of the diseases of the eye, and it was at Oxford, thirty-six years ago, that he prepared and showed the first pathological exhibit displayed at a meeting of the Association. Sir W. Macewen was described as a man famous all over the world for his skill in repelling the attacks of those extremely minute and virulent enemies of mankind which were the cause of septic poisoning in wounds, and his brilliant work in this department of surgery had been recognized by the King, who had knighted him. Sir Patrick Manson was introduced as one who had rendered tropical regions fit for habitation by investigating the causes of plagues and fevers, to do which he had made many voyages and had lived for many months at a time in districts infected with these diseases. Sir J. W. Moore was alluded to as having been knighted by Queen Victoria for his medical services to the people of Ireland, and in his books he had laid down the principles invoked by modern science in fighting against fevers and other infectious and contagious diseases. Dr. Osler was referred to as one who had been for many years a leading exponent of the principle that the art of medicine should be based upon the most exact scientific knowledge of the day.

The newly made Doctors were heartily applauded on taking their seats in the semicircle.

President's Reception.—In the afternoon a reception was held by the President of the Association and the members of the Oxford Division in the gardens of Wadham College, but the enjoyment of the numerous visitors was considerably marred by frequent showers of rain. It had been arranged to hold a fencing competition and a sword contest between representatives of Oxford and Cambridge Universities, but owing to the wet weather these were held in the Town Hall. The contest between Oxford and Cambridge resulted in favor of the latter.

Address in Medicine.—This was delivered in the Sheldonian Theater by Sir William Selby Church (see page 223.)

Vice-Chancellor's Conversazione.—This was given in the evening, and was attended by a great throng of people. At the same time a number of demonstrations (many of them illustrated by lantern exhibits) of recent discoveries

were made by Dr. W. J. Smith-Jerome, Dr. Paul Chapman, Professor Haldane, Dr. H. Sankey, Dr. G. Mann, Dr. Farmer, Dr. Walker, Professor Vernon Harcourt, Mr. Ford Robertson, Mr. Henry Wade, Professor W. Sollas, Mr. A. Tutton, and Professor Myers.

Third Day—Thursday, July 28.

The Temperance Breakfast.—The first item in this day's program was the Medical Temperance Breakfast, which was provided, as it has been for many years, by the National Temperance League. Some 200 members accepted the invitation of the League, and this was the largest attendance since the inauguration, and perhaps the most successful. Mr. McAdam Eccles occupied the chair and was supported by the President, Dr. Collier, and other distinguished members of the Association. An address was delivered by Dr. Kelynack, who held that it was fitting once a year at least that, as medical practitioners, they should review their relationship to the question of alcohol, which he then proceeded to do. He was followed by Dr. Collier, who, in a neat speech, claimed to be a life-long advocate of temperance, and said that the cost of the alcohol he had prescribed during the last month, for his twenty-five beds in the infirmary, amounted exactly to a penny three farthings.

Votes of thanks to the League for their hospitality and to the Chairman were heartily accorded.

Leicester the Next Place of Meeting.—At the adjourned general meeting in the afternoon the President reported that the Council had received an invitation from Leicester to hold the annual meeting of the Association there next year. The invitation was cordially accepted.

President-elect.—The President nominated as President-elect Mr. George Cooper Franklin, F.R.C.S., L.R.C.P., surgeon to the Leicester Infirmary. In the absence of the President-elect, Dr. Pope, President-elect of the Midland Branch of the British Medical Association, gave a very cordial welcome to the Association to meet at Leicester next year.

Address in Surgery.—This was delivered by Sir William Macewen at the Sheldonian Theater before a large and appreciative audience (see page 224).

In the afternoon garden parties were held at Headington Hill Hall, at the invitation of Mr. Geo. Herbert Morrell, M.P., and Mrs. Morrell, at which there were about one thousand persons present, and at the Warneford Asylum, about six hundred accepting the invitation of Dr. and Mrs. Neil.

The Annual Dinner took place in the evening, a company of about three hundred sitting down. The Very Rev. the Dean, the Rev. T. B. Strong, D.D., presided, and the guests included a number of distinguished Oxford men. The usual toasts were proposed by the President, who remarked that they were sorry the Prince of Wales was not able to attend to receive the membership of the Association, and he was sure that if His Royal Highness could have seen his way to do so they would have given him a right royal welcome.

Disease Germs.—Dr. George Bagot Ferguson, ex-President of the Association, delivered the "Popular Lecture" in the hall of the Examination Schools, at 8 o'clock in the evening. He chose as his subject the germs of disease, which he divided into three classes—yeasts, molds (which account for a small number of diseases, such as ringworm), and the bacteria which cause most diseases. The bacteria he compared to dominoes with tails, which are the organs of movement. Bacteria, being short-lived, and multiplying by division every twenty minutes, can in a short time produce enormous numbers. He showed a number of lime-light illustrations, of which the first was a bacteriological laboratory, then followed pictures of stab and streak cultures, the method of inoculating one tube from another, the bacterium termo, the bacillus figurons, the streptococcus erysipelatis, staphylococcus, spirilla sarcinæ, bacillus anthracis in the kidney and lung, and growing on boiled potato, the bacillus of malignant œdema, the coccus of chicken cholera, the pneumococcus, bacillus tuberculosis (which he thought was really not a bacillus but a congery of cocci), the spirillum of relapsing fever, the bacillus of leprosy, the typhoid bacillus, the glanders bacillus, the diphtheria bacillus, the cholera bacillus, etc. The lecture was listened to with rapt attention by a crowded audience, consisting largely of the wives and daughters of members. Dr. Ferguson showed great power of rendering scientific facts not only intelligible but interesting to a lay audience. In his descriptions he freely resorted to all sorts of homely similes.

MEETINGS OF REPRESENTATIVES.

These meetings, under the new organization, followed the annual general meetings on Tuesday and Wednesday, the discussion on the latter day being protracted to a late hour in order to close the subjects referred to the meeting. Sir V. Horsley was reëlected chairman. He said, on assuming the office for the second year, that he would not accept a nomination for a third, as he considered a change in the interest of the Association lest methods should become stereotyped. At a later period, in reply to pressure, he said he would place himself in the hands of the meeting—a response which was heartily cheered.

First Day—Tuesday, July 26.

The subject of medical defense aroused warm discussion. At the Swansea meeting of the previous year, a committee was appointed to consider the question of the Association undertaking medical defense. They now presented a scheme which it was resolved by a large majority to send back to them for reconsideration. There was a strong feeling in favor of medical defence, but it was thought that it should not be made compulsory on all members of the Association to join in it, but that it should be left optional. The Hospital Committee's report was adopted. The following are its provisions: (1) That poverty and sickness shall be conditions of admission to hospital. (2) That no charge shall be made, though voluntary contributions may be accepted. (3) That the production of a subscriber's letter shall cease to be compulsory and that, where possible, the system shall be abolished. (4) That some means of investigating the circumstances of applicants for relief, shall be employed in all medical charities, and that, where possible, a special officer shall be appointed for this work. (5) That, except in emergencies, before a patient is admitted to hospital, evidence shall be obtained that he is not in a position to pay, and (6) that cases of serious accident and severe illness, shall be attended on their first application.

Second Day—Wednesday, July 27.

Action was carried in favor of security of tenure of medical officers of health who, it was pointed out, are now at the mercy of local property owners, and in danger of being dismissed for performing their duty. The question whether it is advisable that medical witnesses engaged on each side in legal cases, should meet in consultation, was referred back to the "Divisions" for consideration. One of the many questions arising out of the Midwives Act, is that of payment of the medical practitioner called upon to assist a midwife. It was decided that some arrangement for payment should be arranged by the health authorities.

The report of the medico-political committee on the remuneration offered by insurance companies for medical examinations, and the character of such examinations, namely that for every full and careful report upon the state of a person's health, the practitioner should receive one guinea, was approved. It was carried unanimously that calf-lymph for vaccination should be supplied by the government free, not only to the public vaccinators, but also to general practitioners.

The practice of opticians examining the eye and pro-

nouncing an opinion and prescribing glasses, was strongly condemned. Two flagrant instances were cited in which a spectacle vendor told a patient he was suffering from Bright's disease when the malady was tobacco amblyopia, and one in which choroidoretinitis was treated as myopia.

The report on the diploma scheme of the Company of Spectacle Makers was adopted. This points out that the testing errors of refraction requires the use of mydriatics, which all but qualified medical men are debarred from. Therefore, the guarantees of qualification in sight testing which the company suggests are illusory. In the second place, the eye being not merely an optical instrument, but a portion of the human body, shares its diseases, which are liable to be misunderstood by unqualified persons. In many cases of grave local and general disease, impairment of sight is the symptom which first attracts the attention and, if the treatment is confined to compensation of refractive errors, the public are exposed to manifest risks. The practice of advertising the names of the hospital staffs in the local press was condemned. The organization of the Local Government Board was strongly condemned, as all power is invested in one official without cabinet rank with a medical officer who has a purely advisory function. A resolution was passed, stating that the President should have cabinet rank and requesting that a royal commission be appointed to inquire into the working of the Board with view to its reformation.

The system adopted by one of the London coroners of ignoring the doctor called to a case and getting a professional pathologist to perform the post-mortem examination was strongly condemned. A deputation has been previously sent to the Lord Chancellor. It was pointed out to him that when the coroner deems an expert pathologist to be necessary, his services should be requisitioned in addition to, and not in place of, the doctor who saw the case during life. As the Lord Chancellor has given no satisfactory reply, it was resolved not to let the matter rest. The best means of bringing pressure to bear on the government, was discussed. It was thought to be unwise to approach the prime minister, who would merely shelve the question. It was resolved to ventilate the matter in the press and to petition the king. A memorandum in support of the Poor Law Medical Officers in Ireland was approved. This involves the recommendation of superannuation allowances for these officers who are liable from the arduous nature of their work to premature breakdown. This principle has been already recognized by Parliament in the case of Poor Law Medical Officers in England.

SECTION OF MEDICINE.

A Discussion on Chronic Renal Disease.—Dr. W. Hale White opened the discussion on this topic, confining himself to the subject of treatment—the treatment of particular symptoms and the treatment of the disease in accordance with theoretical views. In regard to albuminuria, the customary energetic treatment of this condition was a mistake; it was an important help in the diagnosis and prognosis of Bright's disease, but otherwise it was unimportant. Symptoms connected with the cardiovascular system indicated treatment directed to keeping the tension in the arteries as near as possible to that of health without the aid of drugs; if high, to bring it low; if low, as from starvation dietary, to raise it. Rest in bed, the amount of exercise permissible, and the amount of fluid to be allowed were discussed in this relation. Œdema in the chronic tubal variety was best treated by posture, by limiting the fluid drunk, and by purgation. It was a mistake to rely on diuretics for this purpose, but diaphoretics were of use. The employment of puncture and Southey's tubes, taking careful antiseptic precautions, was of most value. Considering the theoretical part of the subject certain, substances were withheld because they were believed to irritate the kidneys; while diuretic drugs might be harmful substances excreted with difficulty, such as lead, mercury, and digitalis should not be given and morphine rarely. Sulphonal and trional should not be given. Alcohol probably produced only a negligiable deleterious influence in chronic renal disease, if in small quantities, seeing that all but 3 to 5 per cent. was used up in the body. As the renal trouble was a degenerative process, a normal diet should be aimed at; no element should be entirely withheld. Perverse dieting in chronic parenchymatous nephritis was even more distressing than in the interstitial form. It was important in this respect to decide the point at which recovery was impossible. Tea, coffee, and tobacco should be used in great moderation, considering their effect on the heart. As a rule, drinking of much water was bad; in tubal nephritis an extra pint of water a day might be tried. Uræmia was generally held to be a form of poisoning, but there was no evidence whatever that the poisonous substances were derived from food; they were probably formed in the body. The only method was to help all the excretory organs, in the hope that the poisons might be removed by one of them; purgation, sweating by hot air bath and pack, transfusion with saline fluid, the injection of pilocarpine, and bleeding in certain cases were recommended. For convulsions, chloroform was sometimes useful. The use of woolen garments, a good climate, such as that of Egypt, and an occasional Turkish bath for a few patients, were recommended. The diarrhœa and vomiting of uræmia should not be checked too soon. For sleeplessness, chloralamid was perhaps the best drug to use. The published accounts of decapsulation of the kidney did not suggest that the method was likely to be adopted permanently.

Professor von Noorden of Frankfort discussed the dietetic treatment of Bright's disease in regard to meat diet according to his well-known views; in regard to water supply, the use of large quantities of fluid were deprecated. The latter had an unfavorable result on dilatation of the heart and asthmatic symptoms. Systematic muscular exertion was advocated, although all fatiguing exercises were to be forbidden. After exercise a transitory rise in albumin might occur, but this was unimportant; the great point was that the state of the heart greatly improved. Dr. Oertel's rules might well be followed, as in heart disease Carbonic acid waters for baths and weak saline springs for drinking were to be desired in a health resort. Another essential point was the connection of Bright's disease with obesity, which was a very dangerous combination. Any reduction of obesity should be very careful and slow. Milk diet should not be too highly recommended.

Sir John W. Moore of Dublin alluded in the first place to the etiology of Bright's disease as met with in Ireland, also the question of diagnosis and the determination of renal sufficiency. The first object of treatment was to relieve strain on the vessels, the second was eliminary, and the third to relieve the strain on the heart. In chronic nephritis the kidneys should be kept flushed with pure soft water sparing nitrogenous diet being employed, while renal patients were better without alcohol, even in small quantities. Elimination should be encouraged, not only through the kidneys by draughts of pure soft water, purgation, diaphoresis, but also by the lungs; to this end the open-air treatment was to be recommended and wintering in a good climate as Egypt, Algeria, Cyprus, or Sicily. At home oxygen inhalations might be used, in uræmic dyspnœa especially. Open-air exercise was good. Of drugs—benzoate of sodium and urotropin were sometimes good. General dropsy acted the part of an eliminant. The indication for preventing cardiac failure were to increase the power of the left ventricle, to reduce the pressure in the right, and to lower arterial pressure. The use of digitalis, iron, arsenic, and strychnine was with the first object; to relieve the right ventricle, hot air baths, pilocarpine occasionally, and bleeding; to reduce the arterial tension, nitrites,

iodides, and restricted diet, etc. The administration of macerated fresh kidneys was alluded to.

Dr. James Tyson of Philadelphia agreed as to the absurdity of the distinction between red meat and white meat in Bright's disease; the use of excess of water was deprecated Mild cases occurred which hardly needed treatment. In the treatment of uræmia morphine was better borne in parenchymatous cases than in others and in some cases might be given with good results. Chloralamid was often of much value, but in some cases it seemed to set up excitement during unconsciousness. Renal asthma, so called, was usually a cardiac dyspnœa and was best treated by agents to reduce arterial pressure, as the nitrites. The œdema of the lungs caused by pilocarpine was counteracted by atropine, which, however, was not usually indicated. Decapsulation of the kidney was referred to and two cases described; it might in parenchymatous nephritis cause prolongation of life.

Sir William Broadbent also deprecated starvation and the use of too large quantities of water, but a tumbler night and morning was much more useful than if taken with food. The loss of albumin was not an important part of the malady. The specific gravity of the urine told much more, and the amount of albumin present. The most important guide to treatment was the arterial tension; cases in which it was diminished were very rare. To reduce the tension mild mercurial aperients were in his opinion much more valuable than other purgatives, even those producing more purgation. By relieving this tension the worst symptoms of uræmia were alleviated. Uræmic convulsions were probably entirely circulatory in their origin; such might occur where there had been no albuminuria. The intracranial pressure being determined by the arterial pressure, caused obstruction to the capillary circulation in the brain, and hence the convulsions. For such bleeding was often of great value. In threatened uræmia a hot bath might determine an attack of convulsions, possibly by increasing the action of the heart.

Professor Robert Saundby alluded to the mistake of supposing that nephritis was an incurable disease. All renal albuminuria did not mean Bright's disease. The curability of Bright's disease was best seen in those cases which were associated with pregnancy. The inflammatory process subsided and left sufficient kidney substance to carry on the renal function.

Dr. Samuel West said that even in acute nephritis patients were kept far too long on a low diet. Granular kidney cases, perhaps above all others, stood dieting badly. All extracts of meat should be avoided, and alcohol in excess, also overwork and worry. The treatment was chiefly symptomatic and the question of a possible internal secretion was alluded to, but it was pointed out that the use of renal extracts depended at present on clinical experience alone. For excessive arterial tension drugs usually used were somewhat dangerous because their action was followed by depression; for lowered tension, in which case the patient was ill, digitalis might be used. Oscillating tensions, even diurnal variations, were sometimes observed. Uræmia was either chronic or acute, and these two forms differed essentially. Acute uræmia suggested a toxin causation and one probably derived from the tissues of the body; intravenous injections and oxidizing agents might destroy these; thus purgation diaphoresis, possible venesection, and intravenous injection and the inhalation of oxygen were indicated.

Dr. Rose Bradford said that in chronic renal disease the eliminating functions of the kidney were much impaired; therefore, the diet should be so modified as to reduce the work of the kidney as much as possible. The albuminuria was not, he thought, of so little importance as some had held; in some forms the amount of albumin that might be lost in twenty-four hours was equivalent to two pints of milk. A more liberal diet than milk diet was of use even if the albuminuria was slightly increased thereby. An albuminuria was often the relic of an antecedent damage, and not evidence of any active disease. There were a few cases of Bright's disease which made considerable general improvement on a pure milk diet for a prolonged time, and in these it should be employed; if the general health did not improve, then a more generous proteid diet was indicated. The treatment of uræmia complicating acute renal disease was different and more satisfactory than that of chronic renal disease. The bowel was the preferable channel of excretion to influence rather than the skin. Morphine was perhaps particularly useful in the cases with epileptiform seizures and dyspnœa, but not with dropsy and fluid in the chest. Venesection for uræmia and headache and followed by copious transfusion were of much value. There was no reason for admitting the existence of an internal renal secretion and there was little to be said in favor of the use of renal extracts.

Dr. James Barr alluded to the preventive methods as applied to Bright's disease and alluded to the value of the cyroscope in appreciating the onset of the conditions leading up to degeneration of the vessels and kidney. The disease, he thought, ought not, if properly treated, to affect the longevity of the individual greatly. He would have alcohol avoided, also an excess of nitrogenous food. Diet, exercise, and clothing were the chief points to be attended to.

Dr. D. Newman protested against the indiscriminate decapsulation of the kidney and described the effect of operation in renal calculus and movable kidney on the albuminuria and presence of tube casts; also to the value of simple incision in renal affections.

Dr. Gore thought that in the treatment of chronic renal disease it must be remembered that there were two channels of toxæmia, one the absorption of toxins by the bowel and the other from waste products from the tissues not being eliminated by the skin.

Acute Leukæmia.—Dr. McCrae of the Johns Hopkins Hospital presented a report on five cases of this disease showing evidence for a rapid destruction of red blood-corpuscles. The speaker urged that attention should be specially directed to the bone marrow, and held that the condition was a general profound anæmia with leukæmia.

Croupous Pneumonia in Children.—Dr. Samuel West read a paper on a disseminated form of croupous pneumonia in children or primary bronchopneumonia having a pneumococcal bacteriology and differing from that of bronchopneumonia secondary to bronchitis.

Dr. Armstrong, medical officer to Wellington College, read a paper on functional albuminuria.

Second Day—Thursday, July 28.

Treatment of Tuberculous Pleural Effusion and Pneumothorax.—Dr. William Osler opened this discussion. Clinically, he said, pleurisy with effusion was pyogenic, pneumonic, or tuberculous, and in the absence of evidence of any etiology of the two former, a tuberculous origin might, with confidence, be predicated, and for the purposes of local treatment it was advisable to consider every case tuberculous unless clear evidence existed to the contrary. The value of early and repeated aspiration in the acute cases; drug treatment, whether ever useful; and the local and general treatment of the condition, were the special subjects suggested for discussion. Of late years, the tendency has been to tap for the effusion itself before the fever had subsided. Of twenty-two cases under his own care, twenty were healed by tapping; among these, five were chronic cases and four were discharged improved; of the fifteen acute cases all were discharged cured. The removal of the fluid seemed sometimes to be directly curative, the fever almost at once failing; this might be by clearing the lymph channels or, in some unexplained way, as in tuberculous peritonitis. It did no harm at any rate. In the chronic serous exudate, the greatest difficulty was experienced from reaccumulation of the fluid. Were there any remedies which directly influenced the absorption

of fluid from the chest? The salicylates seemed to help in the reduction of the fever, but in the tuberculous cases they did not seem to do any real good. Iodides as absorbents were of doubtful efficacy; in the chronic cases, at any rate, they were of no use. A large blister stimulated absorption. So soon as the fever had fallen in an acute case, systematic pulmonary gymnastics should be commenced; if the patient were in bed, by blowing water from one Wollf's bottle into another; if the patient were out of bed, any sort of inspiratory exercise was useful if persisted in. Later, ordinary breathing exercises should be employed, morning and evening. Every patient who had had tuberculous pleurisy should be regarded with suspicion and subjected afterward to careful and prolonged general treatment. The treatment of pneumothorax was unsatisfactory from the associated condition. In large pneumothorax it was better to do nothing; but from whatever cause it arose the acute suffocative pneumothorax demanded immediate operation by incision of the trocar. A perfectly free opening of the chest wall should be made. If pus were present and if the tuberculous disease were limited to one lung, resection of the rib might be employed.

Dr. George A. Gibson of Edinburgh was still in considerable doubt as to the certain diagnosis of tuberculous pleurisy, but in some cases an examination of the urine might show the diplococcus of rheumatism, thus negativing their tuberculous nature. In tuberculous pleurisy, after a limited period of rest, active exercises were strongly indicated. In certain obstinate cases the use of tuberculin injections had been, in his experience, gratifying. In regard to suddenly developed pneumothorax, recovery was almost invariably the rule, with a few days rest followed by graduated exercises; the recovery might possibly be assisted by previously existing adhesions.

Dr. Stanley Boyd, in reference to pneumothorax, said that the acute cases certainly demanded prompt surgical help. In the cases developing in the course of early tubercle of the lung, and limited entirely, or almost so, to one side, occasional aspiration and the open air method gave good results, but the question arose whether surgical treatment could not be started early, before the pleura had become thickened and the fluid purulent; treatment in the way of slow drainage through a fine cannula, which was not kept too long in one place. The danger was that of establishing a pyothorax.

Dr. Samuel West rather doubted if there were such a thing as a rheumatic pleurisy. Pleuritic effusion did not as a rule change their character, but they might easily be changed by accidental infection. The aspirator was a dangerous instrument. The rapid extraction of fluid in the presence of adhesion might lead to rupture of the lung and to other less serious untoward circumstances. Early, as compared with later, paracenteses did not seem to make much difference on the course of the case. From cases of obstinate pleural effusion he had observed it was clear that fluid might be present, compressing the lung for many months, even as many as eighteen, without causing adhesions to form. Tuberculous empyemata had a worse prognosis than other forms; they should be treated on the same general lines and might be washed out freely if that were indicated. The routine excision of ribs was not necessary. Even if a portion of rib were not removed and pressure of the tube on the bone caused denudation of the periosteum of the bone that was not of great importance. The state of the cavity should be frequently ascertained by the use of the probe. Eslander's operation—removing practically the whole of the side of the chest—was a very dangerous operation and anything short of it was an absurdity. In the majority of cases of acute pneumothorax an operation was urged, relief being obtained by tapping, or if repeated tapping did not give relief then the side of the chest should be opened. If air alone were present, the patient might be left and it would be absorbed. If fluid formed it was necessary to find out if it were serum or pus, but the fluid usually lay in a sort of saucer in the diaphragm, which was not easy to get at. If pus were present operation was indicated. The prognosis of pneumothorax, if neglected, was very bad. Directly the fluid was found to be purulent the side should be washed out and treated on general lines and many recoveries would often occur.

Dr. Nathan Raw said that in the majority of pleural effusions the best treatment was aspiration. Of thirteen cases of pneumothorax under his care, two were treated by incision, both of which contained pus and were tuberculous; these rapidly became septic and death followed. Two others which were treated by aspiration and, although containing pus, recovered. Opening the chest seemed to tend to septicity. Ordinary cases, unless with serious and abrupt symptoms of dyspnœa, should be left alone.

Dr. R. W. Philip said that a lymphocytosis in a pleural effusion had an important diagnostic bearing; tuberculin was of use in the diagnosis of difficult cases. If no evident reason to the contrary, for the time and for the purposes of treatment, cases of pleurisy should be considered as tuberculous. Free exposure to open air seemed to obviate the tendency to the occurrence of pleurisy with effusion in phthisis. Diet, and especially raw meat diet, had a beneficial effect on such pleurisies. Cases should be tapped early, when once was often enough. The fewer drugs that were used the better. It was important that the patient should not pass from under observation as soon as the pleurisy with effusion had disappeared.

Dr. T. D. Ackland thought the difficulty in treatment came in when the fluid was purulent. In young persons, in children and in acute cases, in ordinary pleurisies, the fluid should be left unless urgent symptoms supervened. The tuberculous cases, if chronic, and if the effusion were in a small quantity, were better left alone. The presence of fluid had not seemed, in his experience, to lead to the formation of adhesions. If pus were present it was important to determine whether the condition was a local tuberculous abscess and curable, or part of a general infection; in the latter case it were better left alone. It was, as had been said, very easy to open the pleural cavity and very difficult to close it. A tuberculous purulent effusion in the pleura was usually free from pyogenic organism, but if opened infection was almost sure to occur. Enormous hemorrhagic effusions might occur, and for these frequent tappings were, on the whole, the safest and best. When pus was withdrawn some boracic solution might be substituted for it. It might be that tapping and removal of some rib, thus allowing the chest wall to fall in without opening the pleura, the advantages of both methods might be obtained without the disadvantages. In cases of pyopneumothorax, especially those with a bronchial fistula, operation should be done; also if the pus were pointing externally.

Dr. J. Barr thought that in all cases of tuberculous pleurisy effusion, early removal of the fluid by siphon was desirable. He had recommended the injection of sterilized air to replace the fluid removed, the method of which he described.

Dr. J. E. Squire thought that sudden danger in acute pneumothorax was of rare occurrence and the urgent stage was usually short—an hour or two—so that a large proportion of the cases might be safely left without operative interference. If effusion were serious, let it be left alone if not too large; if purulent, let it be removed as soon as possible, and frequently by opening the chest. Dr. Osler, in reply, thought the chief point was the benefit of early tapping. There was an advantage in favor of the syphon.

Dr. Nathan Raw then read a paper on this subject, based on a series of 600 necropsies. The tubercle of the lung was by inhalation, that of the intestine by nutritive substances and usually by in-

fected milk. Human and bovine tuberculosis, he maintained, were varieties of the same infection, and tabes mesenterica was, he believed, always bovine. In 3,000 cases of adult phthisis he had found the glands of joints affected in only fourteen cases; gland and joint and bone tuberculosis, which were diseases of early life, were probably bovine in origin. Even the lungs seemed to be attacked by two different kinds of tubercle, one a rapid and the other a slow and insidious infection. He had never yet found a case of abdominal tuberculosis in a child that had been suckled by its mother. Many such cases of a mild type recovered absolutely, the bacilli never spreading beyond the glands. Bovine tuberculosis was probably more virulent for children than human tubercle; he had never met with a case among children, even of phthisical mothers, who had been only fed at the breast. Scrofulous glands in the neck were probably a local infection derived through the tonsils from tuberculous milk. When tuberculosis was stamped out among cattle it was to be predicted that infantile tubercle would disappear, too. It was a matter for observation whether a serum of bovine tuberculosis would confer an immunity against human tubercle.

Dr. Mitchell Stevens read a paper on the clinical features of splenic anæmia.

Dr. Lewis Jones one on the character of the faradic current.

Mr. Hastings Gilford gave a demonstration of ateliosis.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held May 16, 1904.

Dr. Alexander Lambert, Chairman.

Specimen of an Appendix.—Dr. Frederick Holme Wiggin presented a specimen of an appendix which was of unusual interest. One week ago a physician, thirty-eight years old, came to him and stated that, for three months, he had had intense pain in the abdomen in the mornings, and, after driving, in the cæcal region. His pulse and temperature were normal and there was slight tenderness upon deep pressure over the cæcum. Operation was advised and performed. The appendix was found to be large and much thickened and, at the junction of the appendix with the cæcum, there was a great deal of thickened tissue. In the appendix were found four concretions, one of them being near the junction with the cæcum and buried in a deep hole, and he believed that it would have perforated in a very short time if left alone. There was a slight peritonitis at this junction of the appendix with the cæcum. The case was of interest because of the mildness of the symptoms and also their indefiniteness.

Dr. Alexander Lambert referred to the case of a very athletic young man who had a history of having had pain over the appendix for three or four hours and he decided to remove that organ. Two enteroliths were found within it, one small one at the tip and a large one at the other end measuring three-eighths of an inch in length.

Cerebrospinal Meningitis.—Dr. Thomas Wood Hastings presented this paper. Since the introduction of lumbar puncture the spinal fluid had been studied with some success in various ailments and aided in differentiating them. The fourth lumbar space he considered the best place for the operation because, at this point, the dura mater was more firmly attached. The space was on a line from one superior spine of the ilium to the other. Seldom would the needle become obstructed when properly performed. The amount of fluid removed under various conditions ranged from a few drops to 50 c.c. or even 100 c.c., especially when there was much pressure. For diagnostic purposes only 5 or 10 c.c. are necessary. The chemical analysis of the fluid to-day was of comparatively little value. The physical examination of the fluid showed whether it was clear, cloudy, or hemorrhagic. A cloudy fluid rarely meant infection. In meningeal affections the examination of the cells removed from the fluid differentiated the tuberculous from the non-tuberculous cases Post-mortem examinations have led to the identification of certain bacilli and cocci, such as the bacilli of tuberculosis, of typhoid fever, of pseudo-influenza, of glanders, of anthrax, and of other affections. There had also been found streptococcus pyogenes, staphylococcus pyogenes citreus, and the diplococcus cellulosus and others. The infection may be a mixed one. He referred to a remarkable study of meningitis which was presented to the New York Pathological Society in December, 1902 (Medical Record, February 7, 1903, page 235). Failure to find germs in these cases had been reported; an examination of the fluid late in the disease often gave negative results. Sometimes fluid from a single puncture introduced in two tubes gave positive results in one and negative results in the other. The isolation and identification of the various bacteria he did not consider to be especially difficult. The findings of the diplococcus intercellularis meningitidis of Weichselbaum in the spinal fluid would lead to a correct diagnosis. Out of fifty-three spinal fluids examined fourteen were found to be infectious; of these fourteen, thirteen showed the diplococcus intercellularis of Weichselbaum and the other the pneumococcus.

Dr. Joseph E. Winters considered the clinical symptoms, saying that this disease beggared all description, and attempts to describe it would be utterly useless. On May 4 he saw in consultation a child four and one-half years old who had fallen on the sidewalk and hit his forehead. Two days later it was noticed that his swallowing was peculiar. The next day trismus was present, a diagnosis of tetanus made, and the question of using the antitoxin came up. The temperature was 102.5°. Owing to the marked involvement of the sensorium, he decided that it was a case of cerebrospinal meningitis and not tetanus; the only motor symptom was the trismus. The day following, the temperature rose to 107° and the patient died, and the autopsy report showed an extensive fibrinous exudate at the base of the brain but none in the spinal region, although there were many diplococci in the spinal sac. He saw another case in a child three years old. A physician, in attempting to remove a foreign body from the ear, pushed it through the drum. Later an aurist made an incision behind the ear and extracted a good sized bean from the middle ear. The child recovered rapidly. Eight days after being discharged as cured he suddenly began to have vomiting and abdominal pains. The temperature was 106°. There was tremulousness of the hands, but not of the legs. There was tenderness in the dorsal region. There was some stiffness of the neck with evidences of extreme vertigo and dizziness. A diagnosis of cerebrospinal meningitis was made. The temperature reached 107° and the patient died. A large, robust girl was preparing for school and suddenly was taken with vomiting and headache and in six hours and a quarter from the onset was dead. A boy left his home one morning to visit his grandmother and was taken with pain in the left ankle and two or three hours later was taken home in a cab When the physician saw him he had severe abdominal pain, and a diagnosis of appendicitis was made, and an ice-bag was applied. Later a diagnosis was made of cerebrospinal meningitis and the disease ran un uneventful course. When apparently well he was suddenly seized with violent vomiting, which was uncontrollable for days. The patient was kept under the influence of morphine, was given peptonized milk per rectum and the boy recovered. At a convent in Peekskill four girls were taken ill at the same time with severe vomiting. In one of the children it was noted that the pupil suddenly dilated and remained dilated for some seconds and then suddenly contracted, and this excited the suspicion of cerebrospinal meningitis. The four girls died, and at autopsy the following day they all presented the typical lesions of the disease.

No general description would be applicable to a disease

of this kind, but it seemed to the speaker that a diagnosis could be made from the rapidity of the pulse, the marked involvement of the sensorium, upon the extreme tremor, the sudden change in the disposition of the patient, the great fear and, also, the marked evidence of vertigo.

All cases that had a sudden and violent onset terminated fatally, and cases with a gradual onset, as a rule, ended in recovery. Cases that present a sunken countenance were grave. Great rapidity of the pulse, mottled condition of the skin, and marked involvement of the sensorium were of bad prognostic import.

Dr. Morris Manges took up the consideration of the disease as it affects the adult. He said he was surprised at the incompleteness of the picture presented, nothing being said regarding the rash, or any characteristic changes in the nervous system or the condition of the urine. He said there was a striking difference between the rashes as they occurred in children and in adults. In children at the Mt. Sinai Hospital the rash was very slight, while in adults it was, as a rule, very abundant and was herpes-like at the angles of the mouth and below the chin. The rash was petechial in character. At the knees and elbows it was similar to the cutis anserina but had a more deep color, as if the cuticle had been rubbed off. The condition of the pupils was variable. There was also the deeply injected eye, more or less abundant secretion, ecchymosis about the conjunctiva, and strabismus. The question of headache he considered to be of importance. When the patient recovered from the coma there was usually headache. The posture was quite characteristic, the patient being curled up and disliking being disturbed. The vomiting occurred late in many cases. The condition of the urine offered many interesting features from a diagnostic standpoint. A hemorrhagic nephritis might be a valuable symptom and one might mistake the condition for uremic coma Sugar in the urine might occur. He recalled one case in which the disease seemed to be ushered in with sugar in the urine and diabetic coma was at once thought of. In another case he saw this year, sugar in the urine was an early symptom. The reflexes might be exaggerated but they usually became abolished. Babinski's sign and the Kernig phenomena were of value. Babinski's sign, as a rule, was absent in adults. The disease as it existed in children and in adults ran a different course. There was a high leucocytic count, as a rule. One of the most important features for consideration in this disease, from both a diagnostic and a therapeutic standpoint, was lumbar puncture. At the Mount Sinai Hospital one of the cases admitted was a young patient, forty-eight years old, who came in in coma and the only history obtainable was that the patient had been ill but two hours with vomiting and headache and then became comatose. There was absence of patellar reflex and injection of the eyes, which made him suspicious of cerebrospinal meningitis. Lumbar puncture was performed and only ten drops of fluid obtained, but enough to enable Dr. E. Libman to demonstrate the Diplococcus intracellularis. He did not believe that lumbar puncture was done often enough, and thought that, in cases in which sudden death had occurred with relapses, if lumbar puncture had been resorted to early, many of these cases would have recovered. Sometimes this procedure may not be of great value because of rapid re-collection. In spite of lumbar puncture many cases will run their course, and he believed this was due to the fact that proper technique had not been established. The cases in which he had injected lysol warranted its further employment. In addition, hot baths (104° F.) for half an hour, associated with massage, were of value, but they should be resorted to from the beginning of the disease.

Dr. William M. Leszynsky said he had seen twelve or fourteen cases of cerebrospinal meningitis during the past winter. He referred to one case, a child, nine or ten years old, who had all the characteristic symptoms of the disease, such as rigidity of the neck, opisthotonos, loss of knee-jerks, Kernig's symptom, etc. The fluid was examined and showed the Diplococcus intercellularis of Weichselbaum and polynuclear leucocytes in abundance The child had a temperature of 103°, but there was not much disturbance of the sensorium. One c.c. of a one-per-cent. solution of lysol was injected, which was followed by considerable reaction and a rise in temperature to 104°. The symptoms rapidly subsided, and the patient gradually improved.

Dr. Leszynsky recalled another instance of a child in whom no lysol injection was made. The Diplococcus intercellulosus was obtained and the symptoms seemed to progress slowly, and later gave evidence of a chronic cerebrospinal meningitis; the child became more and more emaciated and finally died from exhaustion. He laid great stress upon the loss of knee-jerks in the early stage of the disease, which he ascribed to cerebral irritation producing inhibition. Later in the disease the knee-jerks returned. He was rather surprised that Dr. Winters did not refer to the use of lumbar puncture. He had seen the case referred to by Dr. Winters, occurring in an adult with trismus and which came to autopsy, showing undoubted signs of a leptomeningitis. He believed it was as yet an open question regarding the value of the lysol injections in these cases.

Dr. Charles H. Lewis had seen five cases which presented the characteristic symptoms, and he said he felt inclined to try lysol injections. The diagnosis had been made in these cases without lumbar puncture.

Dr. A. Palmer Dudley said he wished to consider lumbar puncture from a surgeon's standpoint. He did not think it should be attempted in young children unless they were first anæsthetized. He did not think that the medicated lumbar puncture would have much effect upon the brain because, in injecting cocaine, he had found that its influence did not extend above the diaphragm. He had sometimes failed to get the fluid in the very aged or the very young because of the dry spinal canal.

Dr. James J. Walsh spoke of the possibility of the disease being distributed by tramps, as it was supposed to be in Europe.

Dr. Francis Huber said that he had seen as many as fifty cases of the disease at Gouverneur Hospital and many more in consultation. He said that it should be borne in mind that lumbar puncture done on a healthy subject differed from one done on a patient with pathological conditions in which there was an excess of fluid. In order to influence the brain pressure, at least 8 or 10 c.c. must be removed in children, and in adults a great deal more. He spoke of the value of hypodermoclysis as a means of diluting the toxins; in one case in which this was employed with lumbar puncture the patient was doing very well. In one case he had performed lumbar puncture as many as fifteen times, and he did not hesitate to remove large quantities of fluid, from seven to fourteen drachms, and he never noticed any unpleasant symptoms follow this. Lumbar puncture was valuable not only as a means of diagnosis but also as a therapeutic aid.

Dr. Alexander Lambert said that as yet no treatment employed at Bellevue Hospital seemed to have any effect upon the disease.

History of the Work Done in the Legal Department.—James Taylor Lewis, Esq., made a brief report of the work done during the past three years in investigating and prosecuting illegal practitioners of medicine. Close upon 700 complaints had been investigated where charges had been made that they were practising medicine illegally and 129 cases had been prosecuted, 51 women and 78 men. In 123 cases the evidence had been obtained through agents of the association and in 6 from outside sources. Of the 129, 123 had been won and 3 had been lost. During the first year the average fine had been $45, during the second year $67, and during the past year $85. In 11 instances sentence had been suspended. Referring to midwives, he said that they really had a "Midwife Protective Association," and that

one standing high in it had privately informed him that the "County Association" had them "scared to death."

The defence of suits of alleged malpractice brought against members of the association had been very successful. Mr. Lewis said this would continue until November next and then, because of the amalgamation of the two county societies, it would be discontinued unless arranged for at that time. He thought a continuance of this work by the legal department would result, in the near future, in a discontinuance of any such efforts on the part of the laity.

Retirement of the Chairman.—Dr. ALEXANDER LAMBERT, in retiring from the chair, said he wished to thank the members for their hearty coöperation in the carrying out of the work of the association which to-night met for the last time as the New York County Medical Association.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE OPTICAL DICTIONARY: AN OPTICAL AND OPHTHALMOLOGICAL GLOSSARY OF ENGLISH TERMS, SYMBOLS, AND ABBREVIATIONS, TOGETHER WITH THE ENGLISH EQUIVALENTS OF SOME FRENCH AND GERMAN TERMS. Edited by CHARLES HYATT-WOOLF, F.R.P.S. 12mo, 166 pages, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $1 net.

TWENTY-SEVENTH ANNUAL REPORT OF THE BOARD OF HEALTH OF THE STATE OF NEW JERSEY AND REPORT OF THE BUREAU OF VITAL STATISTICS. 1903. 8vo, 682 pages, muslin.

THE LYMPHATICS—GENERAL ANATOMY OF THE LYMPHATICS. By G. DELAMERE. SPECIAL STUDY OF THE LYMPHATICS IN DIFFERENT PARTS OF THE BODY. By P. POIRIER and B. CUNÉO. Authorized English Edition Edited and Translated by Cecil H. Leaf, M.A., M.B., F.R.C.S. 8vo, 301 pages, illustrated, muslin. W. T. Keener & Co., Chicago. Price, $5 net.

A TEXTBOOK OF HUMAN PHYSIOLOGY. By ALBERT P. BRUBAKER, A.M., M.D. 8vo, 699 pages. With colored plates and 354 illustrations. Muslin. P. Blakiston's Son & Company, Philadelphia. Price, $4, net.

PHYSIKALISCH-MEDIZINISCHE MONATSHEFTE — ZEITSCHRIFT FÜR DIE PHYSIKALISCHE RICHTUNG IN DER MEDIZIN, MIT BESONDERER BERÜCKSICHTIGUNG DER RADIOLOGIE. Herausgegeben von Privatdozent Dr. H. Kraft und Dr. med. B. Wiesner. 1. Jahrgang, Heft 2, Mai, 1904. 4to, 66 pages, illustrated. Dr. jur. Demcker, Berlin W. 15.

THE SURGERY OF THE HEART AND LUNGS: A History and Résumé of Surgical Conditions Found Therein, and Experimental and Clinical Research in Man and Lower Animals, with Reference to Pneumonotomy, and Cardiotomy, and Cardiorrhaphy. By BENJAMIN MERRILL RICKETTS, Ph.B., M.D. 8vo, 510 pages, illustrated, muslin. The Grafton Press, New York.

A REFERENCE HANDBOOK OF THE MEDICAL SCIENCES. Edited by ALBERT H. BUCK, M.D. Volume VIII. 4to, 784 pages. Illustrated by chromo-lithographs and 435 half-tone and wood engravings. Muslin. William Wood & Company, New York.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 6, 1904:

	Cases.	Deaths.
Measles	133	6
Diphtheria and croup	232	33
Scarlet fever	68	2
Smallpox	3	...
Varicella	11	...
Tuberculosis	366	146
Typhoid fever	67	13
Cerebrospinal meningitis	...	...

Dog Oil in Tuberculosis.—The keeper of the dog pound in Chicago, says the *Medical Times*, reports an active demand for dead dogs for their oil. This, he says, is a specific for consumption, and he proposes that the city shall go into the manufacturing business, as the demand is large and increasing. This report supports those who have contended that the value of cod-liver oil depended largely on the proportion of dog oil and other cheap diluents that it contained.

Health Report.—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, U. S. and Marine Hospital Service, during the week ended August 6, 1904.

A POSSIBLE CAUSE OF HIGH-TENSION PULSE IN NEPHRITIS.*

By W. H. THOMSON, M.D., LL.D.,
NEW YORK.
PHYSICIAN TO ROOSEVELT HOSPITAL.

In a patient whom I saw in consultation some years ago in a condition of status epilepticus induced by acute alcoholism, I found a pulse of high tension unequaled in my experience, except in some cases of puerperal eclampsia. He was a healthy man with perfectly healthy arteries, but now those vessels were so universally and extraordinarily contracted that it seemed as if his heart were beating against one and the same well-nigh insuperable obstruction wherever a pulse could be felt. Such excessive arterial ischæmia is certainly a striking phenomenon, and its mode of production is worthy of special investigation. Without doubt it can be ascribed only to the activity of some powerful vasoconstricting agent, but this can scarcely operate solely by stimulation of the vasoconstrictor nerves, and indicates rather a direct action on the arterial muscular tissue itself. This case, therefore, first suggested to me to make an examination into the conditions which lead to arterial tension in general, and particularly in renal affections, with the special purpose of determining in them the date of its occurrence.

I now feel assured that a high-tension pulse is not only one of the most persistent accompaniments of many forms of kidney disease, but that it sets in too soon to be primarily the result of any change whatever in arterial texture, just as no muscular cramp is primarily due to a textural change in the muscle cramped. In other words, high-tension pulse in nephritis is originally due to a general cramp of the muscular layer of the arterial walls, which cramp continues so long as the specific excittant of the muscular coat continues to circulate in the blood.

But while the early development of high tension in acute nephritis seems to imply the rapid charging of the blood with such an agent, its subsequent persistence, according to the persistence of the nephritis itself, raises other questions of high interest. In repeated instances of an acute, gradually changing into a chronic, nephritis, I have found the tension remain all along just the same as at first, while in cases which recover increased tension is quite the last symptom to disappear. Therefore, if high pressure can be assigned as a leading factor in producing changes in the arterial walls, ranging from endarteritis to atheromatous degeneration, that factor of strain is present from the very beginning of the renal disorder rather than as a late consequence thereof. This has led me to reverse the steps in the etiology of many common forms of arterial degenerations, so that instead of regarding endarteritis as I formerly did, as the cause of high-tension pulse, it is rather high tension which causes the endarteritis, of course most signally in the arterioles. I now believe in this being the true order in the genesis of most vascular sclerotic changes, and that we have possibly been misled by the coexistence of high tension with extensive endarteritis obliterans into regarding this symptom as generally the simple mechanical result of channels blocked by gross alterations in their walls. That after such organic changes have actually occurred the accessible arteries will be found overfull and tense goes without saying; but what we would emphasize is that the arterial ischæmia antedates the sclerosis and owns quite another cause for its production.

Another deduction from these premises seems to me to be highly probable. If, as a concomitant of nephritis an agent be circulating in the blood with the property of inducing universal arterial constriction, the consequent strain on the left ventricle of the heart must be much greater than would be caused by any mere discrete, though extensive, changes in the walls of the main arteries. Such changes we often find in senile arteries, without accompanying pronounced cardiac hypertrophy or dilatation. But I cannot conceive of a more certain cause of increased labor for the heart, with all which that fact would entail, than the presence of any agent which induces a prolonged narrowing of every artery and arteriole the body over. Moreover, it seems very probable that such a generally acting agent may alone cause sudden or acute dilatation of the heart, as I have noted in a number of instances when the most typical symptoms of acute dilatation went along with high-tension pulse in arteries which were everywhere contracted, but nevertheless perfectly smooth throughout. In one of the most striking examples of the kind, the most careful palpation of the accessible arteries failed to show the least signs of tortuousness of the vessels or of atheromatous changes in their coats.

What the actual nature of this agent is, and whether it be produced in the kidneys themselves or in some other organs, must at present be wholly conjectural. However, the now familiar physiological properties of the internal secretion of the adrenals, those glands which are topically so closely related to the kidneys, offer a remarkably close parallel in every particular to the apparent properties of the tension-producing agent in nephritis. The first fact which we would advert to is the extraordinary minuteness of the dose of suprarenal extract which is capable of exciting universal arterial contraction, amounting, according to Schäffer, to only $\frac{1}{800}$ of a grain in an adult man. All experimenters also agree that the active principle, or adrenalin, does not act on the arteries through their nervous mechanism, but directly upon their musculature, and that even skeletal muscles do not escape its operation. Its action upon the heart is also very specific, and if the vagi be cut or paralyzed by atropine, the heart's action becomes so violent, and

*Read at the meeting of the Association of American Physicians, 1904.

the rise in tension is so enormous, as to suggest the question whether a like combination of a vagus paralyzing poison with excess of adrenalin may not occur in those grave crises which we encounter in puerperal eclampsia.

Another suggestive fact derived from experimental researches, first fully described by Oliver* and confirmed by Schäffer, Vincent, and others, is, in Oliver's words, the enormous diminution produced by suprarenal extract in the volume of the kidney in Roy's oncometer. This condition of the kidney cannot fail materially to interfere with its secretory functions, particularly in its elimination of urea, and I feel convinced that the diminution in the average daily output of urea in cases of kidney disease characterized by persistent high-tension pulse may be assigned with much probability to this cause.

Before reaching this conclusion, however, certain clinical facts should be taken into account. A decrease in the average normal excretion of urea is no criterion of either the degree or even of the existence of kidney disease. On the one hand, in some advanced cases of parenchymatous nephritis with general anasarca, abundant albuminuria and marked so-called uræmic symptoms, I have found the daily percentage of excretion of urea vary but little from normal. On the other hand, I have notes of thirteen patients in my private practice carefully observed, most of them for many months, in whom the daily excretion of urea has been from one-half to one-fourth what it ought to be, considering their weight, age, diet, etc., and yet in no one of them had any evidences of kidney disease, either chemical or microscopical or cardiovascular, been detectable. One and all of these patients are chronic invalids, but with symptoms characteristic of the term we vaguely name "neurasthenia," and with evidences of persistent gastrointestinal rather than of persistent renal disorders. I am inclined to ascribe their condition to deficient formation rather than to deficient elimination of urea, and I think my surmise is borne out by the results of treatment. With only one exception in the whole list the pulse is of low instead of high tension. Conversely persistent high-tension pulse may go along with free or normal excretion of urea. This I have found in gout. But, on the other hand, when nephritis becomes fully developed in gouty patients, the urea output falls as in other forms of interstitial nephritis.

These clinical facts, however, do not militate against the inference that except in gout a high-tension pulse goes with a contracted kidney, and that a contracted kindey is *pro tanto* incapable of a normal excretion of urea. If, therefore, the kidney be only functionally contracted, or partially so, and not yet too far sclerosed, the administration of an efficient vasodilator ought to be followed by an increased excretion of urea. This would furnish a palpable test, free from the uncertainties which so often surround inferences from clinical observations on the effects of drugs, for the greater or less quantity of urea is a simple fact and not a theory. Accordingly I have made a series of observations on the effects upon urea excretion of full doses of aconite, in patients with chronic kidney disease marked by high-tension pulse, and in the majority of them with accompanying cardiovascular changes. I chose aconite because I regard it as the most certain and efficient vasodilator which we possess; and in saying so I merely wish to remark that as a veteran teacher of the materia medica I have long held that laboratory experiments on animals as regards the various cardiovascular agents can scarcely set aside the conclusions from careful clinical observations on man. I venture to say that any one who can recognize high tension when it is present will find that tension yield more certainly and more permanently when the aconite dose begins to tell than by any other agent except veratrum viride or free venesection. The superiority in this respect of aconite to the nitrites is very marked, for even with the tetranitrate of erythrol in full doses the change in the pulse is too evanescent and too irregular to allow it to be compared with aconite in real efficiency against the chronic high tension of nephritis. Well aware that this is no occasion for adducing a series of clinical histories, I will, in conclusion, merely give the briefest outline of three illustrative cases of the effects of aconite on urea elimination:

Case 1.—A lady, aged sixty years, suddenly fainted on rising from the table, and was found by her physician with all the symptoms of acute dilatation of the heart. I first saw her in consultation in November, 1901. Merely changing her position in bed caused cyanosis and vertigo. I found the left ventricle much dilated, the heart impulse could not be felt, at the apex the sounds were very indistinct, while the aortic second sound was accentuated. The radials and other arteries felt perfectly smooth, but very small, and the pulse was of high tension. Every variety of vasodilators and of heart stimulants were administered perseveringly for two months, such as the nitrites, including the tetranitrate of erythrol, along with strychnine, caffeine, sparteine, strophanthus, and digitalin, besides sodium iodide, arsenic, and tincture of iron, but without avail. The patient continued unable to have her head raised, while uræmic gastrointestinal symptoms developed, with alarming attacks of dyspnœa and syncope, mild delirium, pains in the head, and twitchings of the muscles of the face and extremities. The urine continued to be deficient in amount and the daily output of urea, which was constantly estimated by her physician, amounted to only 8 grams the day before I recommended that all the other medication be stopped, and the tincture of aconite in 5-drop doses be given every three hours day and night. Her physician, in a note to me, says of her subsequent history: "In a few days improvement in all her symptoms was perceptible; her digestion became better; mental and nervous symptoms disappeared; the arterial tension disappeared; the daily output of urea rose from 8 grams to 32 grams; the character of the heart action improved; the apex impulse became perceptible, and slowly increased in force, and the pulse became regular and fuller. Within a week the patient sat up, supported by a bed-rack for ten minutes, without marked change in the pulse."

The aconite was continued for six months in the same doses. The patient slowly improved, and sat out of bed from six to eight hours daily, going out to drive and taking other gentle exercise. Twice the dose of aconite was reduced, but the return to high tension and diminution of the urea output to 13.5 grams daily, with return of symptoms of cardiac weakness, caused the resumption of the original dosage.

At the end of six months the aconite was discontinued, and the nitrites were substituted for it for one month. Cardiac weakness and high tension developed again, and the urea fell to 10 grams daily. Aconite was again substituted for the nitrites, and again the heart action and pulse improved, arterial tension lessened, and the urea

Lancet, June, 1896, p. 1622.

increased to 30 grams. After four months more the aconite was discontinued, as vasodilators seemed to be no longer indicated. The patient continues to lead a carefully regulated life, makes and receives visits, takes walks and drives, and has steadily improved in strength and appearance; which improvement has continued to the present time, three and a half years after her first illness.

Case II.—J. M., aged twenty-two years, admitted at the Roosevelt Hospital first in July, 1902, in a state of coma preceded by convulsions. He remained in the hospital treated for chronic Bright's disease until January 13, 1903, when he was discharged "improved." Readmitted after a week for severe headache and vomiting, and remained from January 21 to April 4. The last two examinations of his daily urea excretion during this latter stay were 12.5 and 7.3 grams. Readmitted May 14, 1903, when I examined him. Patient very anæmic and emaciated, heart impulse weak and very diffuse, widely visible above nipple; apex beat five inches from midline in sixth space; apex systolic murmur transmitted to left; marked accentuation of both basic sounds; fine râles over both bases. Orthopnea; arteries thickened; pulse high tension, 132, irregular. Moderate albumin in urine, but full of hyaline and granular casts. Owing to his frequent vomiting, no medication of any kind given, except the tincture of aconite, 5 drops, every three hours. The output of urea that day was 8.1 grams. The urea excretion gradually rose in fifteen days to 23 grams, and the casts disappeared. The aconite was then increased to 8 drops every three hours, and eight days afterward the urea stood at 28 grams, with no albumin or casts. The heart impulse had receded to just within the nipple. On June 9, however, twenty-five days after beginning the aconite, he had an attack of vomiting and of diarrhœa, induced apparently by eating articles surreptitiously brought by his friends, whereupon the urine dropped from 66 ounces the day before to 22 ounces, the urea from 28 grams to 7 grams, with much albumin and casts, and in two days he succumbed.

Case III.—A young man, J. F., aged twenty-four years, with advanced symptoms of two years' standing of cardiovascular changes, headaches, dyspnœa, and repeated epistaxis; increased heart action, with orthopnea, thickened arteries, high-tension pulse; no œdema. Urine: heavy cloud of albumin; many hyaline and granular casts. Urea, 15.5 grams. When put on tincture of aconite 5 drops every three hours, in thirteen days the urea rose to 40.3 grams, the albumin diminished to a faint trace, the casts disappeared,and the headaches and epistaxis ceased, and the dyspnœa was relieved. After taking the aconite for twenty-seven days it was left off altogether to note the effect. For fifteen days thereafter the urea output remained high, but the headaches, epistaxis, albumin, and casts returned, though $\frac{1}{50}$ grain doses of nitroglycerin were freely administered. For the next twenty days the urea output was slowly but steadily diminishing, when suddenly, thirty-six days after discontinuing the aconite, the urine diminished to 26 ounces, the urea dropped to 6.2 grams, with increased albumin and casts. The nitroglycerin was then pushed for three days more, given hypodermically in $\frac{1}{50}$-grain doses every two hours; the third day after this the urea was 10.5 grams, with no improvement. All his old symptoms were returning, and his heart action became very heaving. He was then put on aconite as before, every three hours, and in five days his urine rose to 68 ounces, and the urea to 39.1 grams. After this improvement he could not be persuaded to remain longer in the hospital for further experiment.

It should be stated that in all three of these patients the diet was restricted, milk being the leading article of food.

Besides other hospital cases which I could adduce if there were time, I have full notes of patients in my private practice in whom similar results as regards increased elimination of urea were attained. In some of them it took a week before any definite change was noted. Usually in the second week the urea excretion may become double, triple, or quadruple what it was in the first week, and the excretion remain for a time, as in Case II, higher than normal, considering the diet, age, sex, and weight of the patient.

In some of my private patients who have taken the aconite for a number of months, or for a year, the urea gradually falls to about what would be the normal average for that patient, when I advise its discontinuance and the effect watched, for more than once the urea elimination has fallen so that the aconite had to be resumed to restore it to its proper figure.

As previously remarked, this effect of aconite on urea excretion I have found most marked in cases of chronic interstitial nephritis with cardiovascular changes, especially in patients not far advanced in life. In elderly patients, with extensive endarteritis obliterans and high-tension pulse, no vasodilator can be expected to relieve the ischæmia in vessels which have practically ceased to exist, and aconite has to be used in them with caution, owing to its direct effect on the heart. Yet even in them, if tachycardia be present, a temporary administration of aconite is sometimes apparently very beneficial.

Should my observations on increased urea elimination following on the administration of aconite in kidney disease be confirmed by others, this drug may prove to be a serviceable prophylactic against arterial sclerosis. I am also at present testing its effect on the high-tension pulse of melancholia in the inmates to two large asylums, as in melancholia also as a class the output of urea is low, but my observations are too recent to report the results. In one private patient insane for eigh teen months, with very high tension, but with no kidney disease, the urea elimination has risen in five weeks from 6.2 grams to 20.69 grams. with a distinct, though moderate, improvement in the mental symptoms.

23 East Forty-seventh Street.

Embalmed Beef and Appendicitis.—H. Temple Munsell says that the frequent occurrence of appendicitis in Johannesburg is one of the local medical facts that strike the newcomer most forcibly. The type of case, too, is as a rule more virulent, is frequently fulminating, and imperatively demands surgical intervention more often than in England. When one bears in mind the fact that practically the whole population of the town exists upon frozen meat or upon tinned meat, Mr. Kellett Smith's suggestion that this is a most important cause of appendicitis receives considerable support. Undoubtedly, for some reason or other, fermentative processes in the intestine of a pathological character are of very common occurrence in Johannesburg, manifesting themselves by diarrhœa and flatulent distension, and can hardly fail, Dr. Munsell thinks, to have considerable influence upon the incidence of appendicitis, and upon the virulence of the type that one so commonly observes.—*British Medical Journal.*

TREATMENT OF RUPTURE OF THE POSTERIOR URETHRA.*

By WELLER VAN HOOK, M.D.,
CHICAGO.

The primary treatment of ruptures of the posterior urethra must be directed to the provision of a mode of exit for the urine from the bladder, to the arrest of hemorrhage from the lacerated tissues, and to reunion of the urethra. It is essential that within a comparatively small number of hours after the accident the urine escape or be withdrawn from the bladder; and as the hemorrhage is usually arrested spontaneously, the primary indications might conceivably be satisfied by catheterization. The passing of a catheter under the morbid anatomical conditions present, is difficult or impossible. Its success presupposes that the operator can cause the point of the instrument, after it has left the distal portion of the ruptured tube, to pass through an extensive lake of blood bounded by contused, infiltrated, and perhaps inflamed tissues, to a successful entry into the lacerated proximal extremity, loosely attached to neighboring structures. The feat can be considered well-nigh impossible as a routine method. It is conceivable that a catheter thus passed and left *in situ* for a number of days might drain the bladder and the lacerated tissues, but so fine-spun a theory is controverted by practice, which has shown that in the majority of instances instrumentation almost invariably results in infection, which, if it does not destroy life, makes necessary the opening of the perineal tissues and the drainage of the accumulated fluids by that route. One of the writer's cases shows that regeneration cannot be depended upon, even if conditions are otherwise favorable.

The only rational treatment of complete lacerations of the posterior urethra lies in immediate perineal section.

Since Guyon published,[1] in 1892, the results of his brilliant series of cases illustrating the feasibility of reuniting the severed urethra and excising portions of the tube upon occasion, the views of the profession have undergone a decided change. Koenig had previously advocated resection of the urethra, but his views did not receive wide recognition.

Scores of actual cases in the human subject, as well as experiments upon the lower animals, have shown conclusively that the regenerative power of the urethral tissues is extraordinarily great. The experiments of Ingianni[2] are in this respect especially convincing. He has demonstrated that in the case of dogs extensive portions of the urethra can be restored practically in their entirety, the mucous membrane and the cavernous layers regenerating with great swiftness and completeness, although the muscularis does not reproduce itself. Several centimeters of urethral tissue can in the dog be replaced by the natural regenerative processes without the use of plastics. Clinical experience bearing upon these points is not lacking.

Roser's explanation of the increase in caliber of the urethra after longitudinal section of strictures of the urethra, assuming that the urethra is widened by the contraction of scar tissue in the perineal wound, is not wholly satisfying. A more logical explanation borne out by experimental and clinical fact, is that the epithelium of the urethra, regenerating with great swiftness, spreads over the granulation tissue of the longitudinal urethral wound, thus permanently increasing the caliber of the tube.

The very interesting clinical experience of Ljunggren is strikingly illustrative of the points proved for the dog by Ingianni. The case of Ljunggren[3] was that of a sailor forty-two years old, who three and a half years before his admission to the hospital, fell from a considerable height, alighting astride a beam. In twenty-four hours it was impossible for him to pass his water. Later, however, with much straining and perineal pain, the bloody urine was voided. Omitting the long history of the patient's sufferings from perineal inflammation with abscess formation, we may refer briefly at once to the technique pursued by Ljunggren, who says:

"I made a perineal section and got into an irregular sinuous cavity with ulcerated, infiltrated walls entirely devoid of mucous membrane. Into this cavity opened the urethra. In front as well as behind, the urethral openings were easily found. The infiltrated tissues and the fistulæ were entirely removed by means of excision and both urethral ends were freshened. On account of great diastasis of the urethral ends—almost six centimeters—primary suture was impracticable. I introduced a soft catheter, No. 17, and sutured the perineal soft parts round about with the exception of the middle of the wound, which was drained with iodoform gauze. When, after a month, the gauze was removed, the patient was able to discharge the water normally through the urethra." On account of a fistula, it was necessary to operate again at the end of two months. Ljunggren describes the procedure as follows: "I made a new incision in the old scar, and found that with the exception of a small point at the opening of the fistula, a reproduction of the urethra in the great defect had occurred. The new-formed urethra was somewhat wider than the lumen of the normal part, looking spindle-shaped, dilated most at the middle; the wall was everywhere plane and firm, the inner side smoothly clad with mucous membrane, which passed over directly at the two urethral openings into the normal mucous membrane. The distance between the two urethral ends measured scarcely four and a half centimeters."

After excising the small fistula, the wound was closed over a catheter, which was left fourteen days in the urethra. Sounds were then passed into the bladder. An examination four and a half years after the operation disclosed the fact that the patient had been entirely well, that the urine was passed in a normal thick stream and that no induration existed in the perineum.

This very unusual case must be considered to confirm the observations of Ingianni in so far as concerns the theoretical possibility of the extensive reproduction of the urethra, but that this result cannot be counted upon in actual practice is proved by one of my observations, in which, although the catheter was left in the urethra six weeks by another surgeon, *i.e.* two weeks longer than Ljunggren left the tube in his patient, no considerable regeneration occurred. On the contrary, scar contraction had so far destroyed the lumen of the tube, when an open operation was made some months later, that the proximal end of the urethra could only be found by the use of a small grooved director. The case is as follows:

A. F., aged thirty years, occupation barber, fell October 20, 1903, a distance of five feet, alighting astride an oak plank in such a way as to bring the urethra into sharp contact with the arch of the pubes. Three hours later the patient was seen by Dr. F. K. Burr, who found him suffering but little pain. Blood was oozing from the urethra. The perineum was much distended, the tissues showing marked ecchymosis, which included the scrotum. Eight or nine hours after the accident the bladder became

*Read before the American Association of Railway Surgeons, May, 1904.

distended and, as the patient was unable to void urine, great pain was experienced. Dr. Burr opened the perineum under general anæsthesia and removed a large clot of blood. The proximal end of the urethra could not be found. Hence, a suprapubic incision was made and a catheter was passed from above downward through the entire urethra to drain the bladder. The catheter was left in for six weeks, when it was found that the patient could pass his water naturally to some extent, although the greater part passed by a urinary fistula that discharged upon the perineum. After a few weeks, scar contraction occurred to such an extent that the fistula was much constricted and the bladder was not able to empty itself completely.

At this time he was referred to the clinic of the writer through the kindness of Dr. Burr. It was then found that he was able to pass some urine through the natural channels but only in a fine stream. Moreover, the bladder did not completely empty itself. Under general anæsthesia a sound was passed down to the scar mass in the perineum, which was opened by a median incision. It was then found that the urethra had undergone complete transverse division and that the ends of the tube were united by a scar. By means of a grooved director the end of the proximal portion of the urethra was found and slit up. The scar tissue was excised extensively, and the ends of the urethra, which had been separated by more than an inch, were drawn together with three catgut sutures embracing the muscular coats of the urethra. A catheter was then passed into the bladder through the entire urethra. The size of the catheter was No. 16 or 18 English. The perineal wound was partially sutured and gauze drainage applied.

The gauze was removed on the third day, the catheter on the seventh or eighth day. The perineal wound leaked for a week or ten days, but before the patient left the hospital, on the twenty-second day, the wound had entirely healed, all urine was being passed by the natural channel, and large sounds could be passed with but little discomfort.

A study of the literature of rupture of the posterior urethra by external violence leads to the unavoidable conclusion that primary operations should be resorted to whenever possible under a technique somewhat as follows: In the lithotomy position, with the grooved staff introduced through the urethra into the perineal tissues, a median incision is made, beginning a half inch in front of the rectum and extending forward toward the scrotum an inch to an inch and a half. While the skin may be divided freely, the deep tissues are only to be incised to meet the sound at a point posterior to the bulb of the urethra. Through the incision the sound can usually be felt. The bulb of the urethra may then be drawn forward by means of a blunt hook, and the ends of the urethra must be sought. The distal portion of the urethra is found at once because the sound passes through it. The posterior portion of the urethra is found by one of the following methods:

If the finger be passed over the deep surfaces of the wound, smooth mucous membrane may be felt guiding the operator to the proximal end of the tube. With full exposure of the wound surfaces, the proximal end of the urethra may be found by probing. In a recent case a large probe must be used or even a catheter, but if cicatrization have occurred, a fine probe or a grooved director should be used.

A method of palpation which the writer has never seen mentioned in the literature of the subject and which he believes is original with him, was practised in the following case:

Anthony M. of Rock City, Ill., was caught under a log that fell from a wagon in May, 1903. Dr. C. G. Ives of Pecatonica was called to see him. He in turn called Dr. C. Helm in counsel. Dr. Helm made a perineal urethrotomy, leaving a soft rubber catheter in the bladder. The perineal wound healed, but a fistula, connected with an abcess in the subcutaneous region of the right side of the scrotum and the right thigh, was drained by incision. Sinuses remained, surrounded by dense connective tissue, until, on November 19, Dr. C. Helm and Dr. Walter Helm, in order to lend interest to a clinic which the writer held in Rockford before the members of the Winnebago County Medical Society, generously invited the writer to operate. As had been discovered by Dr. C. Helm and Dr. Ives, the urethra had been ruptured by the fractured os pubis, of which the right ramus was still displaced, although union had occurred.

A sound passed down to the site of injury did not go farther than the point of perineal injury. The external urethra was incised as far as the sound would go, where the urethra could no longer be followed. There was much dense cicatricial tissue about the perineum, rendering the identification of normal parts more difficult. Careful search with the probe failed to disclose the proximal opening. Hemorrhage from small vessels was annoying. Under these circumstances the writer was confronted with two alternatives, according to the usual rules of procedure. In one instance he might pack the perineal wound with gauze for a few minutes in order entirely to arrest hemorrhage and under inspection make a careful search for the urethral opening with a fine probe, expressing urine from the bladder by pressure from above to assist in finding the opening, or he might at once proceed to do a suprapubic cystotomy, and passing an instrument down from above by retrograde catheterization, locate the tube. The first of these procedures would have been entirely rational and proper.

At the moment, however, the following procedure suggested itself as a rapid method of finding the urethra. By palpation with the volar surface of the finger, the urethra could be rolled under the pubic arch as a somewhat flattened cylindrical mass. It was considered that no other tissues or group of tissues could simulate the tube. The mass having been fixed by the fingers against the bone, a longitudinal incision was made through the middle of it. The finger was then introduced into this opening and the slippery mucous membrane was recognized without difficulty. It was then discovered that a diastasis of an inch or an inch and a quarter had taken place. Under the sense of touch the cicatricial tissue between the ends was excised, the tube was somewhat loosened and two catgut sutures were so placed as to bring together the severed ends. A catheter was left in the bladder, although the perineal wound was left patent. The sinuses and abscesses were opened and curetted. Dr. Walter Helm kindly reports that the urethra healed perfectly, but when last seen there was still some discharge from the sinuses leading down to the fractured pelvic bone.

The writer's method for discovering the posterior portion of the urethra is then as follows:

With the patient in the lithotomy position and an adequate perineal wound, place the volar surface of the index-finger against one of the rami of the pubic bone. Cause the finger to follow the arch of the pubes from a point chosen on one side to a point corresponding on the other side. The finger being moved transversely across the perineal structures with no important tissues between it and the rectum, the urethra is necessarily felt between

the finger and the pubic arch. It slips under the finger as a broad, somewhat flattened cylinder.

The urethra being fixed by two fingers against the pubic arch, the soft mass in which it lies may be boldly incised with a knife. The method may be carried out without the aid of inspection if desired. This, of course, will be an advantage where an exact hæmostasis is difficult.

Inspection may aid in finding the urethra, which is recognized by the discovery of its walls, muscular or epithelial, or by the device of forcing urine through the bladder by pressure from above. The urine may be recognized by sight, or if one desire, he may give a dose of potassium iodide before the operation, and at the moment of seeking the proximal end of the urethra, drop a little acetate of lead solution at the point where the urine is expected to appear. The brilliant color of the lead iodide assists in marking the urethral opening. This refinement is scarcely necessary, however.

When the perineum has not been incised, Meinhardt Schmidt[4] recommends in old cases catching the tissues at the side of the opening with the tenaculum snipping away a small piece of tissue and noting the difference in the direction of the urinary stream. This method will probably not be applicable except in unusual cases.

Forgue[5] has found the proximal end of the urethra in three cases of impermeable fistula of the tube by going at once to the end of the urethra where it emerges from the apex of the prostate. The prostate having been located, the urethra is incised just below it and a sound introduced down to the stricture.

The ultimum refugium is to place the patient in the Trendelenburg posture, open the bladder above the pubes and perform a retrograde catheterization. This operation has been performed many times. It should be resorted to without hesitation when the operator has exhausted the other methods of search. But a prolonged application of the simpler methods, exhausting the patient and increasing the danger of infection, is to be strongly condemned.

The extremities of the urethra having been found, they are to be united by catgut stitches, after suitable trimming, and the wound is to be partly closed. The question of leaving a catheter in the urethra has long been discussed, but the weight of opinion is at present against the practice.

When defects of the urethra are great enough to prevent the ends from being approximated without too great tension, several alternatives are open for consideration:

1. The method of Ljunggren, which although successful in his case, cannot be recommended as a routine method, since it makes too great demands upon the regenerative power of the urethral tissues, as was proved by the writer's case, requires the retention of the catheter for a number of days or even weeks, increases the period of healing and probably heightens the danger of infection.

2. The parts of the urethra may be loosened from their bed. Goldmann[6] in one instance has made good a loss of three centimeters of the urethra and eight centimeters in another. He recommends that the urethra be loosened, in cases in which cicatrization has occurred, before the scars are excised. He states that defects of eight centimeters and even more can be made good by the mobilization of the urethra, especially if the lower extremities be extended at the hip-joint during the operation. Koenig had long previously recommended and practised extensive loosening of the urethra.

3. Ekehorn[7] employed an original method, that in appropriate cases may be of great service. In the case of a boy nine years old who had received a severe gunshot wound in the region of the anus and perineum, a defect of the urethra of such great extent was present that, at the operation performed many months after the injury, it was impossible to approximate the ends. The writer describes his technique as follows:

"Behind the scrotum where the anterior urethral stump opened with its posterior end, a curved incision was made, the two limbs of which ran forward and upward on each side of the scrotum and penis about parallel with the spermatic cords to the anterior abdominal wall. With this cut a flap was enclosed which had its base above the anterior abdominal wall and consisted of the scrotum with its contents as well as the penis and urethra. This flap was dissected loose from below upward from the anterior surface of the os pubis to the upper edge of this bone, so that the suspensory ligament of the penis was cut through. That the spermatic cords remained entirely uninjured requires no explanation. After the flap referred to had been separated from the bone, it was very movable and could be drawn down without difficulty, so that the two urethral stumps could be brought together. From the lower end of the symphysis and the neighboring part of the pubic bone a piece about one centimeter thick was nevertheless removed, by which the pubic arch was made somewhat higher." The urethral ends were then united by sutures. Ekehorn claims, from experiments upon the cadaver, that he is able to make good defects of eight centimeters by this method.

A. Cappelon[8] reports a case in which after resection of two centimeters of the strictured urethra. Thiersch grafts were implanted over the entire perineal wound which was left unsutured. Thirteen days afterward the epithelial surface being continuous from one end of the urethra to the other, the edges of the wound were freed of epithelium and brought together with five silkworm gut sutures over a catheter *à demeure* with but slight irregularities of wound-healing. An excellent functional result was obtained, though the writer admits that the length of time between the operation and his report did not justify a final opinion as to the value of the method.

Tyrmos[9] reports a case in which a defect of the perineal urethra was made good by the transplantation of a flap of mucous membrane from the lower lip eight by two centimeters in extent. In a second case a defect of eight centimeters in length was made good by the transplantation of a mucous membrane flap obtained from the resected rectum.

Rochet[10] treated a case of grave stricture of the urethra by cutaneous autoplasty, making an external urethrotomy and suturing into the strictured canal a cutaneous flap taken from the perineum and suturing the border to the edges of the urethra. Rochet has performed this operation twelve times, four of his cases being unsuccessful. Three of the latter were particularly unfavorable and in the fourth case of failure, the flap, which had been cut too narrow at its base, underwent sloughing. In the eight favorable cases, cures were perfect and definite and were the more gratifying because other methods had been unsuccessfully tried before. Colineau[11] has described the same method.

Luebbe[12] refers to a case operated upon by Woelffler, 1888, who, after excision of a stricture of the urethra, implanted upon the wound mucous membrane after the Thiersch method. The material was removed from a case of prolapsus uteri. The grafts took and assisted materially in the production of a new urethra.

Hans Wagner[13] reports a case in which Mikulicz

transplanted the peripheral portion of a urethra which had been extensively injured into the bladder above the symphysis pubis. Wagner's description is very briefly condensed as follows: Paul O., sixteen years old, a previously healthy boy, was injured by the discharge of a shotgun, the muzzle of which was but a few inches from his body. The missiles, carried in a compact mass, destroyed first the lower portion of the rectum and anus, then the perineal urethra and part of the scrotum, the patient having been in a half-sitting posture when the injury occurred.

The primary inflammation having been managed skilfully, some months later an operation was undertaken to enable the patient to empty the bladder in a normal manner. The prostate and the perineal urethra were apparently gone. An incision was made in the median line above the pubes, extending out upon the dorsum of the penis about three centimeters. It was then carried down to the bone, the arch of the pubes being laid bare. After separation of the suspensory ligament, the roots of the corpora cavernosa of the penis were cut through, while the corpus cavernosum urethræ was lifted up uninjured. The dorsal artery and vein were ligated. Next the bladder was laid bare above the symphysis, the perineum opened and tamponaded with gauze. In the upper border of the symphysis, a groove was hollowed out for the corpus cavernosum urethræ. The vault of the bladder was then opened and drawn forward and the bulbous part of the urethra sutured to the bladder with silver wire. A catheter was passed into the bladder through the urethra. Although at first a catheter had to be used, it was possible after six months for the patient to pass the water spontaneously. While the urinary function is reported to have been satisfactory in this case, nothing is said of the generative function.

Guyon[14] warns against immediate repair of the urethra in case of severe laceration. He describes three cases, in two of which the operation was supposed at first to be successful but in the sequel scar contraction obliterated the tube. Marocco[15] also recommends secondary suture.

It is probable that the use of tissues which at the time of operation seemed to be uninjured, but which were destined on account of the traumatism to undergo molecular death, was responsible for the imperfect healing. If this is the correct explanation of the experience of Guyon, the lesson to be drawn from his cases is that the bruised tissue should be removed with sufficient freedom to give assurance that regeneration will be perfect. The large number of cases operated upon successfully by primary suture seems to justify the operation.

Fearing that contraction may take place in new-formed connective tissue, I make it a point to leave no opportunity for this to occur. Contraction is prevented with certainty by passing sounds at regular intervals. The patient readily learns to do this himself.

The after-treatment of perineal urethral resections has received much discussion at the hands of numerous distinguished writers. There is no controversy upon the subject of the use of urinary antiseptics and the administration of large quantities of water. All are agreed that free drainage should be practised. It is the method by which it should be accomplished that has been the subject of most discussion. Some are of the opinion that the catheter should be left in place for a number of days or weeks in order to enable them to almost completely close the perineal wound at once, while others, believing that the perineal wound should be left wide open for drainage, consider the catheter unnecessary.

Lennander[16] refers to an operation performed by Rolet, who, after resection of the uretha, left the catheter in place for thirty-six days. The operator stated that everything healed by first intention.

Koenig has been a consistent opponent of the catheter *à demeure*. Martens,[17] who reviews the work of Koenig in this field for twenty-five years, states that it is Koenig's practice not to suture the lower wall of the urethra and to leave the lower wound open. The catheter *à demeure* is usually not applied.

It is my own experience in a large number of perineal sections and prostatectomies that the use of a catheter *à demeure* is harmful rather than beneficial. As a rule, if the bladder needs immediate drainage by a tube, it is far better to leave a very large catheter or tube in the bladder to pass out of the perineal wound, which is left almost without transverse sutures. The use of the permanent catheter in the presence of infected urine often produces a suppurative urethritis that may result in permanent damage to the canal.

The use of sounds is an absolute necessity, whether the catheter has been applied or not. Conical sounds, are of course, to be selected, and the largest sizes are to be used first. I usually pass large sounds while the patient is asleep at the time of the operation, and after a week or ten days, use a sound one or two sizes smaller than the largest applied during the operation. Nitrous oxide gas anæsthesia is very convenient but by no means indispensable. Cocaine can be used with excellent results. I must agree with Martens when he says these sounds pass easily through the urethra, provided one does not use force.

It is the natural tendency of the tubes of the body that carry fluids to heal of longitudinal wounds even if they are unsutured and patent. Even the terminal fistulæ that are so annoying are almost invariably avoided if the surgeon takes pains to keep granulation tissue thoroughly cauterized and prevents epithelium from lining the fistula.

The permanency of results obtained from these methods has been frequently called into question. If sounds are regularly used, scar contraction is less likely to occur.

Chorea.—Eustace Smith recommends the uses of large doses of ergot in connection with confinement to bed. He gives 3i of the liquid extract well diluted every 3 or 4 hours. He finds that the addition of 1 to 3 drops of liquor strychninæ appears to have a marked effect in quickening the action of the ergot.—*British Medical Journal.*

PRIMITIVE MEDICINE.*

By E. J. KEMPF, M.D.,
JASPER, IND.

History may be defined as consisting of a systematic record of past events with careful attention to their importance, their mutual relations, and their causes and consequences. History is made by man, and is a record of what he has done. This record was made in words, spoken words at first, and written words later on. And as words are the only things that last forever, history is the only relic left us by our forefathers of the ancient day. Looking abroad over the whole world, after the lapse of an unknown number of ages, what have we of the past but the words of poets, philosophers, historians, and orators, who being dead and buried no one knows where, yet speak from their tombs by the power of their thought, and in their immortal works still maintain their dominion over inferior minds through all posterity.

Words are vehicles by which thought is made visible to the eye, audible to the ear, and intelligible to the mind of another; they are the palpable forms of ideas, without which these would be as intangible as the spirit that conceives or the breath that would utter them. Undoubtedly, traditions of what had been said, as well as what had been done, by eminent personages were perpetuated in families through all generations; but as it was enough for the purposes of tradition that events and discourses should be substantially true, every one who repeated either would do so in his own language according to his talent.

Medicine in its early form is intimately allied to magic. It would soon be discovered by accident that certain plants produced effects, both good and bad, upon the bodies of men and animals, and the reverence arising from their real virtues would lead to ascribing to them all manner of imaginary ones. The laws of nature being little known, one thing was not more incredible than another; and effects were assigned to causes in the most arbitrary and accidental way. The Rosicrucian physicians treated a case of wounding by applying the salve to the weapon instead of the wound itself; and this may be taken as a type of magical as contrasted with rational medicine. The operation of magical medicines was not, as is the case with those of the modern pharmacopœia, confined to physical effects on living bodies to which they were applied; associated with incantations and other ceremonies, as they always were, they could be made to produce almost any desired effect—raise or lay storms; fertilize a field or blast it; kill or cure a man, absent as well as present; and give the power of predicting future events. By virtue of magic medicine the medicine-man in all the ages of unscientific medicine has also been the priest and the prophet of the more advanced people, and the rain-makers of the savages.

The origin of medicine, as such, was probably contemporaneous with the origin of civilization. But for thousands of years medicine was not a science, only an undigested collection of experimental notions, vaguely described, disfigured by tradition, and often made useless by superstition and ignorance. Though the earlier periods of medical history are so mixed up with myth and fable as to be very uncertain, for us the history of medicine must necessarily commence with the written history of medical events. The first medical historian gained his medical information from the sayings of his fathers, and from the practices of his contemporaries, and with commendable prudence he put the words of tradition on to paper of some kind for the benefit of future generations. The early history of medicine is entirely legendary, and is made up of stories of the lives of the first doctors, who either lived on this earth, or were created by the imagination of the first historians, who made up a history from the legends and traditions handed down to them by their ancestors. The object of this paper is to consider in a brief way the primitive stage of medicine, or the history of medicine preceding the life and labors of the great Hippocrates, who is rightly named the "Father of Medicine." To do this in an intelligible manner it becomes necessary to make use of the known history of the primitive people who existed centuries before the times of Hippocrates, and others who, though having lived many years afterward, it is safe to say pursued the same medical ways handed down to them by their forefathers. Primitive medicine may be said to exist even to this day among some of the tribes of uncivilized people, and the medical historian must be allowed to draw on their traditions in order to give a useful description of what may be granted to have existed in the earlier or primitive times of the human race.

How a belief in imaginary virtues of things may grow out of the experience of their real virtues is indicated by Dr. Livingstone, when speaking of the beliefs in rain-making among the tribes in the heart of Southern Africa. The African priest and the medicine-man is one and the same, and his chief function is to make the clouds give out rain. The preparations for this purpose are various—charcoal made of burnt bats; internal parts of animals, as lion's hearts and hairy calculi from the bowels of old cows; serpent's skins and vertebræ; and every kind of tuber, bulb, root, and plant to be found in the country. "Although you disbelieve their efficacy in charming the clouds to pour out their refreshing treasures, yet, conscious that civility is useful everywhere, you kindly state that you think they are mistaken as to their power; the rain doctor selects a particularly bulbous root, pounds it, and administers a cold infusion to a sheep, which in five minutes afterward expires in convulsions. Part of the same bulb is converted into smoke, and ascends toward the sky; rain follows in a day or two. The inference is obvious." The religion of this part of Africa may be characterized as medicine-worship. In a village of the Balonda, Dr. Livingstone saw two pots with charms or medicines kept in a little shed, like idols in a niche. For an idol they sometimes take a piece of wood and carve a human head on it, or simply a crooked stick, when there is no professed carver to be had; but there is nothing divine about it until it is dotted over with a mixture of medicine and red ochre. Packets of medicine are worn as charms about the person, to ward off evils of all kinds. The female chief Manenko was hung all over with such charms; and when she had to cross a river, her travelling doctor waved medicines over her, and she took some in her hand, to save her from drowning.

Amulets were worn by some of the tribes of Southern Africa, as well as by other uncivilized people. An amulet is an object worn as a charm. It is often a stone or piece of metal, with an inscription or some figures engraved on it, and is generally suspended from the neck, and worn as a preservative against sickness, witchcraft, etc. The beliefs in the virtues of amulets is not extinct among the vulgar, who thus foolishly follow a heathen and savage custom.

The prayers of heathens, whether for blessings or for curses, partake largely of the nature of magical incantations. They are not supposed to act as petitions addressed to a free agent, but an inherent force which even the gods cannot resist. This

*Read before the Dubois County (Ind.) Medical Society.

notion pervades more or less all superstitious worship.

The language of primitive nations is crude and unmanageable, the words being as difficult to weld together as pieces of cast iron; but when one of the priests or medicine-men had, in the form of poetic utterance, fused the words into those rhythmical sequences that please the ear and hang together in the memory, we need not wonder at the power his incantations formed in the ignorant minds of his followers. There was no end to the power ascribed to incantations, especially when accompanied, as they generally were, with the concocting of drugs and other magical rites. They could heal or kill; they could extinguish fire; darken the sun and moon; make fetters burst; blunt a sword; make a limb powerless; destroy a crop; produce rain at will; and do other absurd and impossible things.

The priest, the medicine-man, and the rain-maker was always the same man amongst the primitive people, and being a superstitious and ignorant man himself, he relied on his incantations, his amulets, and his weird actions to gain his point, always being careful to ascribe any failures resulting from his endeavors to some negligence or action of his followers and dupes.

Amongst the vulgar of the civilized peoples of our day, amulets and incantations are still relied on not only for the healing of the sick but also to call up their spirit friends or to gain luck in their speculations.

In the Royal Library of Madrid, and in the Biblioteca Nazionale Centrale of Florence, are preserved two manuscripts which throw light on the practice of sorcery, medicine, and surgery in ancient Mexico, a short review of which is here given:

The native Mexicans practised massage, employed the temazcalli, or sweat-house, performed simple surgical operations, and understood the medicinal value of various plants, and other natural products. Splints were used in the dressing of fractured bones, and in order to retain reduced dislocations until they had healed, inflamed gums were lanced with obsidian knives, aching teeth were extracted, salt was used as an antiseptic, and ground obsidian as a dusting powder. Stiffness of the muscles and joints was treated by the sweat-bath, followed by pinching and squeezing, and sprains by gentle rubbing. Wounds were sutured with human hair, the actual cautery was applied to the edges of the wounds, and venom was drawn out of poisoned wounds by sucking, whilst bleeding was practised in obstinate headaches. Near Montezuma's palace was a garden for the cultivation of indigenous medicinal plants. Capsicum served them as now for the purposes of counter-irritation. The herbs tlalcaote and iztanhiati, and the juice of the agave were used as vulneraries, and the ecusco, cocoiatic, and pepper plant as sternutatories in the treatment of headaches. The Listerian method has its prototype in the employment of the juice of the ulli or the caoutchouc for the exclusion of the air from wounds; while various resins served for the preparation of plasters and incenses. As the betel nut is used in the east, so tobacco was employed by the Mexicans as a masticatory, the bruised leaves being mixed with lime or charcoal; it formed the ye-qualli or tobacco-food, and in the form of pellets was carried about by the persons in small gourds. Under the name of the divine food, the priests used tobacco in combination with dried spiders, scorpions, etc., a mixture not unlike the one recommended by the Reverend Cotton Mather, or Governor's Winthrop favorite prescription of sowbugs. The smoking of tobacco appears to have been less common, and the reed-tobacco, compounded with fragrant substances, was a luxury to be used after banquets and upon festive occasions. The hygiene of the teeth was well looked after, very hot food being avoided, as was the use of cold water after eating hot food. Wooden toothpicks, clean water, and powdered charcoal served for dentifrice. In short, the practice of medicine among these early Mexicans compares very favorably with that in vogue at the time of the landing of the Pilgrim Fathers, as pictured by Oliver Wendel Holmes in his review of the "Medical History of Massachusetts." Many of the ancient nations of South America, we may surmise, had even a brighter medical history, but there are no records left to us of their medical achievements.

In the writings of Dr. Benjamin Rush occurs a description of the Indian medicine, as he had learned about it. The treatment of children among the North-American Indians tended to secure their hereditary firmness of constitution. Their first food is their mother's milk. To harden them against the action of heat and cold (the natural enemies of life among the Indians) they were plunged into cold water. In order to facilitate their being moved from place to place, and at the same time to preserve their shape, they were tied to a board, where they laid on their backs for from six to eighteen months. The mother sucked her child till it was two years old, and sometimes longer, and during this time refused the embraces of her husband.

The Indians had no set time for eating, but obeyed the gentle appetites of nature as often as they were called by them. Their diet was of a mixed nature, both animal and vegetable. After whole days spent in the chase or war, they often committed those excesses in eating to which long abstinences could not fail of prompting them. It was a common thing to see them spend three or four hours in satisfying their hunger. This, however, was occasioned not more by the quantity they ate than by the pains they took in masticating it. It was also a practice amongst the Indians never to drink before meals, when they either worked or travelled. They were much given to the cold bath, to painting of the face and body, and to dancing. It was a remarkable fact that there were no deformed Indians, except those injured by the accidents of the chase and war.

The Indian women menstruated at a late period of life, between the eighteenth and twentieth year, had easy labors, and there was hardly a period in the interval between the eruption and the ceasing of the menses in which they were not pregnant or giving suck. The custom of late marriages among the Indians is assigned as a cause of the considerable vigor enjoyed by them, and of the more certain health of the suckling child.

The diseases prevalent among the Indians consisted principally of fevers, and diseases produced by cold, such as pleurisy, pneumonia, rheumatism, etc., also dysentery. Smallpox, measles, tuberculosis, etc., are diseases contracted by the intercourse of the Indians with the Europeans. Scurvy was unknown to them, so also gout, insanity, and nervous disease, until the White Man learned him to drink alcoholic liquors. The Indian never was afflicted with intestinal worms, and the periods of dentition in infancy and childhood were unaccompanied by disease.

The remedies of the Indians, like their diseases, were simple and few in number. When sick the Indian refused all kinds of stimulating aliments, but was allowed to drink plentifully of cold water.

Sweating was much used by the Indians, and their mode of procuring this evacuation was as

follows: The patient was confined to a close tent or wigwam, over a hole in the earth, in which a red-hot stone was placed; a quantity of water was thrown upon the stone, which instantly involved the patient in a cloud of vapor and sweat; in this condition he rushed out and plunged himself into a river, whence he retired to his bed.

Purging and vomiting were also in vogue among the Indians, American ipecacuanha being used for the latter purpose. Bleeding, which was produced by means of sharp stones and thorns, they confined entirely to the part affected. The Indians employed a caustic in obstinate pains in the following manner: A piece of rotten wood, called punk, was placed upon the part affected and afterward set on fire; the fire gradually consumed the wood, and its ashes burned a hole in the flesh.

The treatment of the sick Indian was greatly in the hands of the so-called medicine-man, who frequently relied on amulets and incantations; if not to cure his patients, at least to give their confidence and superstition trust. The priest and the medicine-man was one and the same, and his chief functions were to make clouds give out rain and to cure those who were seriously ill.

It is remarkable how similar primitive medicine is among the uncivilized people or savages of the Eastern Hemisphere as well as of the Western Continent. Primitive medicine consisted principally of the empirical and superstitious employment of simple vegetable remedies in conjunction with amulets and incantations, used by the priests or so-called medicine-men.

The history of Chinese medicine shows that it consisted of a jumble of superstition and empiricism; and that it has been with but little change handed down in the same conditions from the ancient days to the present time. The Chinese School of Medicine is a theoretical and not a practical one. The theoretical writings of the Chinese authors is not equalled in extent perhaps by that of any other nation. As a specimen, the "Pan Tran" may be named. It is a work on materia medica and therapeutics, in forty octavo volumes, and contains a list of seven hundred and fifty-six other works from which it was compiled.

A succession of changes has occurred in the theory and practice of Chinese medicine similar to those which have marked different eras in the history of our profession in Europe. The first great master in Chinese medical history was Cheung Chung King, who lived in the second century of our era, and was contemporary with Galen, a Roman writer on medicine, who is second only to Hippocrates in fame as a compiler of medical lore. King was distinguished for his heroic practice, giving medicine by the pound instead of the ounce or grain. His system of medicine prevailed a thousand years among the Chinese, when the second great writer, Lo Shau Chau, appeared, the peculiarity of whose practice consisted in using bitter and refrigerating medicines.

In the thirteenth century (our era) appeared the third great master, Li Tung Tan, who introduced the elevating and strengthening plan of treatment. This system prevailed for two centuries, when it was opposed by Chan Tan Ki, the fourth great author, whose practice was directed to alternating and lowering the powers of nature.

There were no medical schools or colleges in the history of China for the education of physicians. Those who wished to practise, learned from private preceptors and from books, the therapeutical means in common use. The study of the books which treat of the established modes of treatment entitled a man to the standing which belonged to the regular medical profession. This left the field open to everybody, and the result was doctors were numberless.

As a very good idea may be gained from Chinese medicine of the condition of primitive medicine, it will be my endeavor to give a short description of their system of medicine.

The following are some of the absurd notions taught in their books on the subject of anatomy: The larynx goes through the lungs to the heart; there are three tubes communicating from the heart to the spleen, liver, and kidneys; the spleen lies between the stomach and diaphragm, the food passing from the spleen to the stomach, and thence by the pylorus into the large intestine.

They believed that the small intestines are connected with the heart, and the urine passes through them into the bladder, separating from the fæces at the caput coli; that the large intestines are connected with the lungs, and lie in the loins, having sixteen convolutions; that the skull, pelvis, arm, and leg are each single bones. The soul is considered to reside in the liver, and courage in the gall-bladder. Every square inch of the surface of the body had its appropriate name, the location and relations of which, anatomically and therapeutically, formed an important part of the physician's knowledge.

The Chinese possessed a knowledge of the circulation of the blood 2,000 years before the birth of Christ. In an ancient book appears this: "Everything that gives motion, thrusts forward some movable body, and everything that is moved, either gives place readily or makes resistance. Thus, as the blood and spirits are in continual motion, they strike against the vessels in which they are contained, and, therefore, must necessarily arise a beating of the pulse." The most incorrect notions continued, however, to be entertained as to the course of the blood and the means by which it permeates every part of the body and the Chinese made no distinction between arteries and veins.

One of the most interesting facts connected with the history of Chinese medicine, is the extraordinary attention their physicians have given to the study of the pulse. A most wonderful and complicated system of examining the pulse had been developed and practised for centuries. By feeling the pulse alone they professed to tell the seat of a disease, its intensity, and in the fatal cases, how long it will be before death will take place. They profess to decide from the pulse if a woman is pregnant, to tell the stage of her pregnancy, and the sex of the fœtus.

To understand how it is that Chinese physicians judge of disease by the pulse, it will be necessary to explain briefly their theories with reference to the sympathetic relations of the various parts of the body and the changes wrought in them by morbific causes.

They lay down two natural principles of life, viz., vital heat and radical moisture, of which the blood and the spirits are the vehicles. In all departments of philosophy they recognize two principles, which they call the dual powers, or the male and female principles of nature, the action and reaction of which give rise to all the phenomena observed in organic and inorganic nature, and it is these two principles which constitute the vital heat and radical moisture.

The body is divided into right and left parts, each of which has an eye, shoulder and arm, leg and feet. A second division is transverse, into high, middle, and lower parts; and a third into viscera and intestines. The radical moisture is lodged in the six viscera, the heart, spleen, and kidney on the left; and the lung, liver, and kidney on the right.

The vital heat resided in the six intestines, viz., the small intestines, gall-bladder, and the ureter on the left; and the large intestine, stomach, and ureter on the right. It is from these organs that the heat and moisture are distributed by the blood and spirits over the whole body. This is accomplished by means of twelve canals, each one of which takes its origin from one of the twelve seats of heat and moisture.

A very close sympathy is believed to exist between the various internal organs, and each of these is considered to have an intimate relation to one of the five natural elements, earth, air, metals, water, and fire. Thus fire rules the heart; air, the liver and gall-bladder; water, the kidneys; metals, the lungs; and earth, the spleen and stomach. The agreement and disagreement of these elements with the various organs deranges the circulation of heat and moisture, and gives rise to alterations and disease.

They believed that every internal part had its pulse, of which that at the wrist is the echo or representative.

To show how exceedingly complicated were their systems of diagnosis and prognosis by means of the pulse, I give a list of twenty-four varieties of pulse distinguished from each other at six different points. They are as follows:

1. A floating pulse.
2. A deep pulse.
3. A slow pulse.
4. A quick pulse.
5. A slippery pulse.
6. A rough pulse.
7. A substantial pulse.
8. An empty pulse.
9. A vibrating pulse.
10. A failing pulse.
11. A rapid pulse.
12. A moderate pulse.
13. A large and broad pulse.
14. A small and minute pulse.
15. A long or protracted pulse.
16. A short pulse.
17. An impeded pulse.
18. A sudden or throbbing pulse.
19. A hidden pulse.
20. A moving pulse.
21. A strong pulse.
22. A weak pulse.
23. A hard pulse.
24. A contracted pulse.

To each of these twenty-four varieties of pulse are attached indications for each of the six points where it is felt, and it is from these that the scientific physician judges of the condition of internal organs. As an illustration take the seventeenth variety, which is the "impeded pulse."

The "impeded pulse" in the left wrist,
At first point, indicates sudden death.
At second point, indicates weakness and perspiration.
At third point, indicates exhaustion of the fluids.

The "impeded pulse" in the right wrist,
At first point, indicates failing of blood in veins.
At second point, indicates water in the stomach.
At third point, indicates life endangered.

Whatever may be thought of the theories upon which this system of examining the pulse is founded, we must give the ancient Chinese physicians the credit of being most persevering observers, and although we may reject both their theories and the indications pointed out in their systems, yet we can readily conceive how it is possible for one long accustomed to this mode of observation to become very skilful in pointing out the phenomena which are developed in the course of diseased action.

The practice of surgery was almost entirely unknown to the Chinese. They possessed no surgical instruments. The treatment of fractures and dislocations was not understood. Teeth were not extracted until they became loose enough to be removed by the fingers. All diseases and injuries requiring surgical interference were beyond the reach of the whole medical faculty.

The only distinctive surgical invention by the Chinese is acupuncture, which they used with great elaboration for rheumatism, gout, and localized pains. This very ancient remedy is still used, especially in the east. Steel needles are made use of, about three inches long, and set in handles. These are passed to the desired depth in the tissues and left there from a few minutes to an hour. The relief to pain afforded by this simple operation is sometimes astonishing, and the wounds are so minute as to be perfectly harmless. Quacks have made use of the remedy extensively, especially during the sixteenth century. The system of treatment known during our present days by the euphonious name of Baunscheidtismus consists of acupuncture.

The department of midwifery has from time immemorial been exclusively in the hands of females. Native females of respectability lift up their hands in horror and amazement at the idea of having male attendants.

As a description of primitive obstetrics, it will be of interest to know how lying-in women are treated in the Celestial Empire.

When labor comes on, the midwife is sent for, and the patient sits on a little stool which is placed inside of a low tub. They think it astonishing that any woman can be so uncleanly as to remain in bed An assistant supports the patient's back and she is always delivered sitting up. It is only in very severe cases that a patient is permitted to lie down. Sometimes they walk about to assist the pains. Medicines are given to expedite delivery, and nearly every woman takes a "hastening pill" at the commencement of labor. The umbilical cord is cut with scissors or a piece of broken porcelain, and is done up in rice flour. The placenta is allowed to come away of itself; but if it is long in doing so, the patient's throat is tickled with a feather and the effort of gagging forces the after-birth away.

After the birth of the child the mother is permitted to lie down a little while, but, as a general thing, she sits up nearly all the time, reclining, perhaps, a little the second day. She is supposed to be able to go about on the third morning and does so. The poorer classes do not lie down at all, but go about their usual work as soon as the labor is over. Among the wealthy they do not lie in bed, but keep their rooms for one month, being unclean, as they say, and no one is permitted to enter except those in attendance, and very near relatives. At the end of the month the mother purifies herself, dresses up, and comes out to a great feast, on which occasion the child is named, and its head, if a boy, is shaved for the first time by a barber.

As soon as the child is born, it is wiped with soft paper and wrapped up in old clothes of any kind; but it is not washed until the third morning. It is fed with soft boiled rice immediately after birth, and continues to have two meals of this per day. Very soon after the labor is over, the mother partakes of rice and pickled ginger, with hard boiled eggs, which have been prepared beforehand. After the second day, if there is no fever, she is allowed chicken, pork, fish, fruit, and whatever she fancies; but everything she takes during the month must be cooked in vinegar and spirits.

No instruments of any kind are used to assist labor, but to what extent the midwife uses manual interference is not so easily discovered. It is doubtless a blessing that no one has invented the obstetrical forceps among the Chinese, while they are so profoundly ignorant of the anatomy of the pelvis and of the mechanism of labor.

Japanese Medicine.—The old school of medicine in Japan was nearly identical with that of China, a melange of superstition and an absurd and utterly artificial system of anatomy and physiology, the result of ages of empirical practice—the latter having led to a more or less correct appreciation

of the use and value of many medicines used by ourselves, *e.g.* mercury, antimony, aconite, etc. In addition to a vast number of plants and minerals, animal substances, such as dried fetal deer, dried lizard's bodies, tiger's claws, teeth, bear's galls, formed an important element of the old pharmacopœia, and other even more repulsive substances were largely used.

In surgery the Japanese were as ignorant as the Chinese. Amputation was not practised by the Japanese, nor did they seem to know anything of the ligature as a means of arresting hemorrhage. They performed the ordinary operation of harelip, and the operation of catheterism was familiar to them, they using a metal catheter. They were conversant with the temporal, carotid, and radial pulse, and recognized the heart as the prime source of the pulse, beyond this the whole subject of anatomy was a mystery to them.

The practice of obstetrics was similar to that of the Chinese. There is, however, a tradition that a celebrated Japanese quack knew of the use of the obstetrical forceps, but that he kept the secret to himself, being a similar story to that of the Chamberlins of British medical history.

Of course, at the present time the practice of medicine and surgery in the Japanese Empire is probably as far advanced as that of any nation on the globe, which was brought about by the miraculous advancement of the Japanese people in all branches of civilization during the last thirty years.

In India, during the eleventh century before Christ, the healing art appears to have been better understood than it was by any of the other nations of the ancient world, but it was still mainly empirical. The priests were both medical men and surgeons during the history of the ancient Indians. In the ancient times the student of philosophy studied all the branches of science. He was a legislator, a physician, as well as a philosopher. In the time when the borderland of history melts into the inscrutable haze of antiquity the men who led Hindu minds were not only the priests and legislators, but they were also the physicians of the people. Gautama, the founder of Buddhism, was the product of the Hindu physiology which flourished for many centuries before the awakement of thought in Greece.

The life of Gautama is second in thrilling interest only to the life and work of Jesus, who came centuries after the Hindu history we are now considering. Gautama was born 500 B. C., at Kapilavastu. The legends and miracles of Gautama are all tempered with dignity as rightly belongs to a teacher and savior of men. "He was a prince, his fellow a paralytic: men were born in pain, to die in fear." Gautama cured them of their bodily ailments and offered them words of consolation for their mental troubles. Old and young, rich and poor, men and women were all welcome to Gautama. His success lay in two elements: his personal beauty and amiability, and the absolute equality of all men in his system.

In the history of antiquity the secrets and learning of the physicians were always in the hands of the priests. It was so in the temples of the ancient Egyptians, it was so in ancient Greece, it was so in Rome, and it has been so in later times. This is due to the fact that owing to ignorance, credulity, and superstition, diseases have at all times been regarded by the ignorant as evidence of divine wrath and chastisement, or of diabolical or occult influences, rather than the effect of natural causes. Hence men have turned ever toward prayers, exorcism, and expiation, especially when exhorted thereto by the priests. This has been the sacerdotal aspect of the practice of medicine of all times. Then, again, it must be remembered that most diseases get well without any treatment—that is, they are self-limited. Other diseases are caused by some obscure defect of the will-power. How easy it is to cure such diseases, especially if one is beautiful of body and excellent of mind enough to pass himself off as some divinely inspired personage, is a matter of history. The power of a great mind over the weaker ones is inestimable, and if it is used to a good purpose for the benefit of mankind, worthy of the praise and admiration of every right-minded man.

The oldest Sanskrit books are called Vedas, from Veda—knowledge. The Susruta, commentator of uncertain date on the Yajur-Veda, speaks throughout of a single class of practitioners who undertook both medical and surgical cases. Surgery enjoyed a high esteem among the Indians of ancient times in very remote periods. "A physician who is not a surgeon," so ran their proverb, "is like a bird with but one wing."

The medical treatment of diseases was excellent, though it was empirical. The training of practitioners was undertaken with great care, consisting, especially, of manual skill and experience. The great and important branch of medicine, anatomy, was an unknown science, which more than anything else hindered the further improvement of medicine and surgery among the Hindoos.

A very copious materia medica was at the services of the Hindoo practitioners, and among their most reliable remedies are noted arsenic, mercury, zinc, and many other substances of permanent value. The ancient Indians appear to have had an ointment that caused the cicatrices of variola to disappear, and they cured the bites of venomous serpents with remedies whose composition has been lost, much to the detriment of mankind.

The early races of India seem to have known the value of massage in the treatment of a great many diseases, for the subject is frequently referred to in the writings of the people from a remote period. It is also a certainty that these people were very well acquainted with the value of baths in controlling fevers and other diseases. The bath most highly valued by them was the sweat bath, followed by the cold plunge.

In diagnosis and prognosis, the Hindoo practitioners of medicine were more skilful than any other physicians of ancient times. For instance, it may be mentioned that ancient Hindu charlatan priests let fall from the end of a straw a drop of oil into the patient's water. If the oil was precipitated and attached itself to the bottom of the vessel, they predicted an unfavorable result; if, on the contrary, it floated, they gave a favorable prognosis. This is, so far as we know, the earliest recorded way of testing the urine for its specific gravity, on the amount of which they based their ideas of the condition of the patient.

In surgery the Hindoo doctors were especially efficient. Surgical instruments skilfully made of steel, to the number of 127, still attest their proficiency in cutting and cauterizing—the latter performed in observance of an aphorism quite Hippocratic in its ring—"What drugs and knives cannot cure may be cured by fire."

Their young surgeons were trained to operate by practising not on animals, or on the dead human subject, but on wax-covered boards, on beasts' skins, or on the succulent plants or fruits. The young surgeon was given instructions how to keep his instruments in order. Their surgical instruments are described as made of steel; and they should have good handles and firm joints, be well

polished, and sharp enough to divide a hair; they should be perfectly clean, and kept in flannel in a wooden box. Bandages, fourteen in number, were fully described, as to the making and the using of them. Splints of a great number and variety were made use of in the treatment of fractures and dislocations.

Some dextrous operations are described by the Hindoo surgeons, such as the rhinoplastic, which is of native origin. Hemorrhage they checked by cold, by compression, and by styptics. The ligature they seem to have known. Amputation was confined to the hand in cases of intractable hemorrhage. Lips or surfaces of wounds they smeared with an arsenical salve. For intussusception, volvulus, and such abdominal lesions they practised laparotomy, while fistula in ano (diagnosed by the speculum) they treated with the knife and corrosives. Fractures were diagnosed, and crepitus was understood; dislocations were classified; wounds were divided into incised, lacerated, contused, etc.; cuts of the face and of the head were sewed up; venesection was practised; leeches and cups were employed; poulticing, fomenting, etc., were done as at present; amputations were performed, hemorrhage being generally controlled with the use of boiling oil; tumors were removed; abdominal dropsy and hydrocele were tapped; hernia was reduced by taxis, and if necessary, operated upon; cataract was removed; and in obstetrics the cæsarean section was employed.

Lithotomy was in no case performed without the sanction of the rajah, who assumed the rôle of consulting physician. The surgeon performed the "sectio lateralis," described during the Roman period by the medical historian Celsus, who, no doubt, copied his operation from the Indians.

The dominant people in Babylonia in its earliest times were the Accadians. They had come originally from the mountains of Elam, to the east of the Tigris, and hence their name Accad, which means "highlanders." They brought with them the art of cuneiform writing, as well as other arts and sciences, amongst them the art of medicine and surgery. And when the Semitic tongue had become prominent, Accadian, now a dead language, was to the Assyrians what the Latin language has been to the nations of Europe: Assyrian scholars translated the Accadian literature into their own language, and their medical knowledge was borrowed from it. Every day is bringing to light new proofs of the influence of the Accadians upon the civilization of the Semitic nations, and through them upon that of Europe. Greece, it is well known, derived its system of weights and measures from the Babylonian standard; but these have been proved to be of Accadian origin. The Greek *mina* or *mna*, the fundamental unit of the Greek monetary system, is the *maneh* of Carchemish, and maneh is found to be an Accadian word, showing the origin of the system. The sexagesmial division of the circle; the sign of the zodiac; a week of seven days named as we now name them, and the seventh day of rest, are all Accadian. It is reasonable to suppose that the ancient Greeks derived the greater part of their medical learning indirectly from the ancient Accadians., from whom they received the benefit of other sciences. The Accadians were great in magic, and the Greek *magos*, a magician, is derived from an Accadian word equivalent to "reverend." This points toward the supposition that the priests of the Accadian nations were also the physicians, and that they relied greatly on magic and the superstition of the people in the treatment of their patients.

The history of the Accadians is of great interest to us as the probable source of the origin of Greek medicine, which was the beginning of our system of medicine. This but illustrates the idea that the history of medicine is not chopped up into distinct periods, but rather that one period of medicine is entwined in the one preceding it. In medical, as in civil history, there is no real break. A continuous thread of learning and practice, though varying in degree, unites the whole. Age after age records new discoveries, as well as the death of theories and practices, which became obsolete because they had no real merit, and in the course of time it has been made apparent to even the most skeptical that medicine is assuming the true aspects of a perfect science and an art.

Assyrian Medicine.—It was a general custom among the Babylonians to expose their sick persons to the view of travellers, in order to learn from them whether they had been afflicted with the like distemper, and by what remedies they had been cured. In those times, therefore, medicine was merely a conjectural and experimental art, entirely depending on results of observations made upon the nature of different diseases, and upon such things as are conducive or prejudicial to health.

Generals, and other officers in the command of troops and armies, did not think a knowledge of physic beneath their dignity, but frequently rendered as much service to the army by their skill in their medical, as they did by their courage and conduct in their military capacity. Botany, or that part of physic which treats of herbs and plants, was very much known, and almost the only branch of the science used in those early times.

In all the ages diseases were alleged to be affected by the touch of the hand of certain persons, who were supposed to communicate a healing virtue to the sufferer. Among the Chaldeans, the Babylonians, the Persians, and many others, the priests affected cures, or threw people into deep sleeps in the shades of the temples, during which the sleeper sometimes had prophetic dreams, and that they otherwise produced effects like those now referred to animal magnetism. Such influences were held to be supernatural, and no doubt they gave power and influence to the priesthood who controlled the art of medicine.

The Persian monarchs always cultivated the science of medicine, and constantly held it in great reputation. The great Cyrus, as is observed by Xenophon, never failed to take a certain number of excellent physicians along with him in the army, rewarding them very liberally, and treating them with particular regard. Cyrus thus only followed a custom that had been anciently established among their generals by the Assyrian people; and the younger Cyrus acted in the same manner. Thus history tells us that Cyrus the great was able to conquer certain nations by ordering the drinking water of his troops to be boiled before using. The troops of Cyrus remained well and active in the field, whilst the enemy died in great numbers of fevers. Then as now, sickness killed more soldiers than did the art of war.

Persian Medicine.—In studying the life of Darius I, the king of the Persians, we read that Darius chanced to have a fall from his horse in hunting, by which he sprained one of his feet in a violent manner, and put his heel out of joint. The Egyptians were then considered the most skilful in physic; for which reason Darius had several physicians of that nation about him. These undertook to cure the king, and exerted all their skill on

so important an occasion; but they were awkward in the operation, and in handling and managing the king's foot, that they put him to incredible pain; so that he passed seven days and seven nights without sleeping. Among the prisoners held by Darius was a celebrated physician of Crotona, whose name was Democedes. He was mentioned to the king by some person, and was sent for immediately, and brought to the king in the condition he was in, with his irons on, and in very poor apparel. The king asked him whether he had any knowledge of physic? At first he denied he had, fearing that if he should give proofs of his skill, he should be detained in Persia, and by that means be forever debarred from returning to his own country, for which he had an exceeding affection. Darius, displeased with his answer, ordered him to be put to the torture. Democedes found it was necessary to own the truth, and therefore offered his services to the king. The first thing which he did was to apply gentle fomentations to the parts affected, and after the swelling was reduced the sprain and dislocation were easily cured.

Democedes, after performing this cure upon the king, was admitted to the honor of eating at the royal table, and was highly respected at the king's capital, Susa. At his intercession, the Egyptian physicians were pardoned, who had been condemned to be hanged for having been less skilful than the Grecian physician; as if they were obliged to answer for the success of their remedies, or that it was a crime not to be able to cure a king.

Democedes had the good fortune to perform another cure, which contributed to raise his credit and reputation still higher. Atossa, one of the king's wives, was attacked with a cancer in her breast. As long as the pain of it was tolerable, she bore it with patience, not being able to prevail on herself, out of modesty, to discover her disorder. But at last she was constrained to it, and sent for Democedes, who promised to cure her, and asked of her a favor in return. The queen engaged her word and was cured. The favor promised the physician was to procure him a journey into his own country; and the queen was not unmindful of her promise. She persuaded the king to send Democedes in company with fifteen Persian noblemen to visit Greece on a diplomat-mission. During the journey Democedes managed to escape to Crotona, as was his purpose, and his fellow-citizens refused to deliver him to the Persians, which nearly resulted in a war between the two countries.

From this sketch we may derive the fact that the Persians had no medical men of learning, but that they hired Egyptians and other physicians to tend to the sick and wounded. If these hired physicians were successful in their undertakings they were richly rewarded and held in high honor, and if they failed to cure their patients hanging was frequently their lot. This strange abuse was the effect of an unlimited power, which is seldom guided by reason and equity, and which being accustomed to see everything give way implicitly to its authority expects that its commands, of whatever nature, should be infallibly performed.

It was during the sixth century before Christ that the Crotonians acquired the reputation of having the ablest physicians, who belonged to the Grecian School of Medicine, which was now in process of development. The importance of this historical fact will be appreciated when we come to consider the Grecian medical history, as giving us the assurance that even during its earlier days Greek medicine was by no means to be despised. A man like Democedes of Croton, who was born about the year 550 B. C., must have possessed great skill and knowledge to be able to cure a queen who was suffering from a painful tumor of the breast, and he certainly did show great skill and common sense in restraining himself from trying to reduce a dislocation of the ankle, which had been bunglingly mistreated, until the swelling and inflammation had been subsided by means of hot fomentations, a procedure, which the most skilful surgeon of to-day would consider a plausible mode of treatment. Were Democedes living now, he could, no doubt, teach us many things which would be of benefit in the way of treatment, things that were lost in the whirligig of time.

We now come to consider the history of the medical practice of the ancient Egyptian people. In the Bibliotheque Nationale at Paris there is preserved a papyrus roll, which belonged to the eleventh dynasty of the Egyptian kings, and was written about 2500 B. C. Yet it is but a copy of a treatise published by a governor or viceroy, Ptah-hotep, who began to reign about 3580 B. C. This, the oldest book known to the world, carries us back about thirty-six centuries before Christ, and does not appear as a first attempt to give instruction, but rather seems to belong to an advanced period of learning. The book opens with a remarkably accurate description of the decrepitness of old age. From the learning displayed in this book we are justified to surmise that medicine was an art, which had been cultivated for many centuries before the date of the Ebers papyrus roll, and that it had reached a very high grade of efficiency.

The Egyptians were the most civilized people of the ancient times, and there are evidences to show that they were possessed of many of the secrets of medicine, some of which may still remain to be rediscovered by our modern savants. Owing to the disappearance of most of the ancient Egyptian literature at the destruction of the Alexandrian library, we at present find only remnants of description of their medical learning.

Thus we read that Joseph commanded his servants and physicians to embalm him after his death, this being about 1700 B. C. Egypt at that time possessed a class of men who practised the healing art, and who also embalmed the dead, which must have both required and furnished a crude idea of anatomy. The writings of that early period relate to us that the practice of medicine of those times was altogether empirical, and based on superstition, and on the experiences gathered up and preserved by the priest of the temples.

From the relics and the remains found in the tombs of the ancient Egyptians, we learn that the art of embalming as practised by the Egyptians of the ancient day reached a high degree of efficiency, such as is perhaps not equaled by the embalmers of the present day.

Relics found in these ancient tombs consisted of cupping-vessels made of cow-horn, lancets, forceps, knives, probes, scissors, etc., this showing that the ancient Egyptians also practised surgery. Artificial teeth were found in mummies; and mummies have also been found with well-set fractures, that had thoroughly healed. Many of these relics are still to be found in the museums of Europe and America.

If the Egyptians did not invent the science of physic, they at least practised it in a rational manner. The sick were not abandoned to the arbitrary will and caprice of the physician. He was obliged to follow fixed rules, which were the observations of old and experienced practitioners and written in the sacred books. While these rules were observed, the

physician was not answerable for the success; otherwise a fatal issue cost him his life. This law checked, indeed, the temerity of empirics; but it also prevented new discoveries, and kept the art from attaining to its just perfection. Every physician, if Herodotus, the historian, may be credited, confined his practice to the cure of diseases of one organ only; thus one physician treated diseases of the eyes, another took care of the teeth, and so on.

Egypt is the birthplace of *Alchemy*, the forerunner of chemistry, *Hermes Trismegistus* being the father of the science. The name is derived from *chemi*, which is the ancient and native name of Egypt. The Egyptions appear to have possessed the greatest amount of chemical knowledge of all the nations of antiquity. They preserved dead bodies from decay, fixed colors from silk, prepared medicines and pigments, as also soap, beer, vinegar, metals, and metallic alloys, common salt, vitriol, soda, sal-ammoniac, glass, enamels, tiles, and painted earthenware.

Physiology was synonymous with natural philosophy among the ancients. With them, a treatise upon the formation of clouds, the precipitation of rain, the absorption of luminous solar rays by the atmosphere, etc., was as much a part of physiology as an essay upon the movements of the heart in animals or the circulation of the sap in plants. At the present time the term is used in a much more restricted sense.

The Materia Medica of the earlier Egyptians embraced the milk of animals, honey, salt, vinegar, etc., the application of raw flesh, ammonia, lard, and the use of prescriptions of draughts, unguents, and injections. Whilst the earlier practice of Egyptian medicine appears to have been rational, without any superstitious intermixtures, the later documents are of an inferior kind, showing the practice of magic and incantations.

Different kinds of *baths* were used by the ancient Egyptians as a religious rite. There is reason to believe that sweat baths followed by a cold plunge were preferred by the physicians as a remedial measure. Baths were frequently followed up with a thorough rubbing down of the entire body with scented oils and salves, specially prepared for the purpose.

Whilst the Egyptians recognized many rules of hygiene, they entertained but a mean opinion of that sort of exercise, which did not contribute to invigorate the body, or improve the health. They were a vigorous people, very much in earnest, and had no time for pleasure, nor for music, which they considered a useless and dangerous diversion, and only fit to enervate the mind.

The earliest notices of surgery occur among the Egyptians, who, as we find represented on obelisk and in temple, practised incisions, scarifications, probably even amputation, long before the date of the Ebers papyrus (3500 B. C.). *Surgery* consists of manual intervention, mediate and intermediate, in all lesions or malformations of the human body. This the earlier Egyptians readily recognized, and surgery was already an art amongst their physicians when medicine proper was but a phase of superstition.

The Egyptians performed castration to furnish eunuchs for the harem, and were even acquainted with the operation of castration of females, in order to keep them from becoming pregnant. The operation of circumcision was practised by them as early as 1996 B. C., long before Abraham the first of the Jewish nation was born, which is but an illustration of the old saying, "there is nothing new under the sun."

Hebrew Medicine.—Moses was not only the God-inspired liberator of his people, but he also possessed all the rare qualities which alone could enable a man to mold half-brutalized hordes of slaves into a great nation. Such a man could only choose the best from the knowledge he acquired from the wise men of the different nations with whom he came into contact during the long and active life necessary to prepare him for his great task.

Moses who was brought up as the son of the daughter of Pharaoh, and who was trained in all the learnings of the Egyptians, Assyrians, and Chaldeans, and who is said to have become a priest, under the name of Osarsiph or Tisithen, and to have been a mighty adept in all the sciences of his adopted country, probably derived many of his hygienic rules, and also his views as to medicine, from the ancient Egyptians and Accadians, which he made use of later on at the time he prepared the rules for the guidance of the Hebrew Nation.

Moses is noted in history as a great legislator and general, and also as a wise and learned man, well-versed in all the knowledge of the times, and it may be surmised that he was well acquainted with the art of medicine as it was then practised. The ten plagues mentioned in Hebrew literature as visiting the Egyptians, and which were not only foretold by Moses, but also to a great extent ameliorated by his efforts, were no doubt visitations of diseases that could have been accounted for by natural explanations, but it served the purpose of Moses rather to mystify such occurrences than to clear them up.

The Bible, which contains the medicine of the Hebrews as taught by Moses, purports to be the word of God; and in spite of all criticism it vindicates its claim. The Bible is in truth the exposition of the spiritual experience of man in his progress from mere creatureship to sonship with God. From the religious standpoint, it is with this understanding only that the Holy Volume should be opened. The Book of Leviticus, the writing of which is attributed to Moses, is largely made up of rules concerning matters of public health. Chapter XI gives directions of what beasts may, and what beasts may not be eaten by the Lord's chosen people; also what fishes, what fowls, what creeping things on the earth are forbidden to be used for food by them. Chapter XII directs the women how to purify themselves after childbirth; directions which might be followed by the women of the present day with benefit to themselves. In this chapter the hygienic measure of circumcision is insisted on in the following paragraph (3): And in the eighth day the flesh of his foreskin shall be circumcised; meaning thereby that if the child be a male child, he is to be circumcised on the eighth day.

In paragraphs 4 and 5 of this chapter the woman is directed to purify herself for thirty and three days after bearing a male child, and for sixty and six days after bearing a female child. By this we understand that the woman should not lie with her husband for at least thirty-three days after her confinement, a rule which ought to be followed by the women of our day.

Chapter XIII of Leviticus gives a description of the diseases of the skin under the name of leprosy and the plague, and how to prevent their spreading. It is more than probable that at this time nearly all diseases of the skin were considered a form of leprosy, and that syphilis was thought to be identical with leprosy.

Chapter XV is designed to regulate the relation of man and wife, and the purification of both under certain conditions. Several of the other chapters

of Leviticus are designed to regulate the sexual life of man. These outlines are still observed in some localities by certain sects, while the hygienic measure of circumcision then insisted upon is still observed as a religious rite among the descendants of Moses.

Next to Moses in medical lore should be mentioned *Solomon*, to whom is attributed a very high degree of knowledge of natural history, and who, according to Josephus, had such perfect knowledge of the properties of all the productions of nature that he availed himself of it to compound remedies extremely useful, some of which had even the virtues necessary to cast out devils.

The medical history of the Jewish nation does not record the name of a single great physician who was not also a priest; indeed, the rules by which the people were governed directed them to go to the priest, and by doing certain things and offering up certain duties, they were to be purified and healed of their afflictions.

Among the ancients contact with a dead body imparted an amount of defilement which numerous ablutions and a multitude of other expiatory practices could scarcely efface. On this point the law of the Jews was in strict harmony with the precepts of their holy religion. We read in Holy Writ:

"He that touches the dead body of any man shall be unclean seven days." "He shall purify himself with it on the third day, and on the seventh day he shall be clean; but if he purify not himself the third day then the seventh day he shall not be clean." "Whosoever toucheth the dead body of any man that is dead, and purifieth not himself, defileth the tabernacle of the Lord; and that soul shall be cut off from Israel: because the water of separation was not sprinkled upon him, he shall be unclean; his uncleanliness is yet upon him." "This is the law, when a man dieth in a tent, and all that is in the tent, shall be unclean seven days."

Of course, under the circumstances anatomy could not be anything but guess-work, and had no chance to become an exact science. And surgery which depends on a knowledge of anatomy for its thorough understanding and practice could not be but imperfect and empirical.

Baths were in great demand by the Jews, and the Mosaic law directs that baths be taken in running water.

"Demoniacs" is no doubt the name given by Jews to persons afflicted with epilepsy, hypochondria, or insanity, diseases of frequent occurrence in the east. It has been known by physicians of all ages that these diseases often recover spontaneously, or suddenly by means not explainable. Such diseases, of course, when cured by means of hypnotism or an impression on the will-power of the afflicted, could be easily classed as miraculously cured. Homer, Herodotus, Euripides, and later writers even during the Christian era, believed that the extraordinary actions and conditions of men, which could not be referred to by known and apparent operations of the mind, must be ascribed to the influence of demons. Such diseases are now, however, better understood although there are no doubt people who still believe in witches and devils.

Phthisis.—It is a comforting doctrine, and economically reassuring, that the tuberculous patient of whatever country or race can be suitably treated not far from his own home. Doubtless climatic factors are of considerable moment. They are all mainly of importance in so far as they encourage the patient to live the open-air life. In only too many instances the good effect wrought is undone at night by sleeping in stuffy and overcrowded rooms. —R. W. Philip.

ALCOHOLISM AND DRUG HABITS; THEIR PATHOLOGY AND TREATMENT.

By KANUTE ARVID ENLIND, M.D.,
SOUTH NORWALK, CONN.
SUPERINTENDENT, FAIRFIELD HALL.

To-day the question of alcoholism and drug addictions are, more than ever, attracting increased attention and study among scientists, statesmen, social reformers, and progressive medical men. Side by side with this deepening appreciation of their deteriorating influence, there has arisen a firm determination to endeavor, by both educational measures and restrictive means, to teach the gravity of these habits, and thereby to prevent, at least, their increase.

From a careful observation of these habits for the past ten years, I have been able to study systematically the physical manifestations of the action of alcohol and the long and continual indiscriminate use of stimulating narcotics and the consequent degenerative changes in the nervous and cerebral cellular tissues.

Before discussing the question of alcoholism further, it would, perhaps, be wise were we to differentiate between the terms alcoholism and dipsomania. An alcoholic patient becomes insane because he drinks; while a dipsomania patient is already insane before he commences to drink. In dipsomania there is an established pathological state of affairs that impels. It is a diseased condition of the cerebral tissues, coupled with a so-called "highly-strung" nervous system.

It can be said, therefore, that alcoholism, rather than being a disease itself, is really a condition produced as a consequence of the action of alcohol on the system; or, in other words, a state of chronic alcoholic poisoning. This same condition of affairs may be said to exist in the system as a consequence of the indiscriminate use of drugs.

The true method of dealing with this condition lies in paying attention to those possible deficiencies which are at the root of the desire for the liquor or drug.

Our foremost pathologists and scientists have a clear recognition of the truth that the habits herein discussed arise from manifestations of acute pathological changes, and that these morbid changes are profound, whether they exist in the kidneys, the minute cerebral arteries, the spinal cord, multipolar cells in the cerebral cortex, or in the nerve cells in general.

We are very often apt to be too general in our statements in reference to these changes, satisfying ourselves with the tortuosity of the vessels of the pia mater, the adhesion of the pia mater to the cerebral cortex, subarachnoid effusions, sclerosis of the cord, sanguineous effusions, extravasations and infractions, degeneration of the walls of the arteries and the alterations in the consistency of the cerebral tissues.

All of these changes do occur, and are of importance as clinical evidence. But even here we must not stop, because as we further investigate, we will discover changes still more decided, more decided even than the marked molecular degeneration, leading up to the partial destruction of the cortical cells, as well as destruction of axis cylinder fiber elsewhere.

The principal considerations are the chemical and histological changes brought about by these poisons in nerve tissue. To fully appreciate these changes we must remember the importance in the constitution of nerve tissue of cholesterin in large quantities and always in combination with the various fatty, bodies found in nerve tissue, and which are unstable

capable of many complex degenerations and all richly permeated with blood.

Particular attention should be paid to the following two facts, viz., that cholesterin is itself an alcohol, and that the fatty bodies found in nerve tissue (of which lecithin is chief) are phosphorized bodies in which phosphoric acid is combined proximately with glycerin. These fatty bodies in combination with neurin and ammonia compounds contain nitrogen, therefore, chemically speaking, we have an alcohol in combination with phosphorus, glycerin, nitrogen, and ammonia, and all in close relationship.

By this relationship, nerve impulse is generated, as, for example, the electric currents which start muscle impulse and contractility.

All of these elements—cholesterin, lecithin, protagon, and neurin—are highly unstable, and the least disturbance of the delicate balance is the first incident of disease. The very slightest deviation from the normal proportion of the elementary constituents of the nervous tissue must be followed by altered physical conditions. In the author's mind there exists no doubt but that alcoholism is pronounced in producing these morbid changes in the structure of nerve tissue, thus interrupting the nerve balance.

Nature fully intended that the nerve should have to contend only with the normal quantity of alcohol of the cholesterin. Interference, therefore, with the normal proportion and the disturbance of the various elements by alcohol accomplish a degeneration. This fact should be thoroughly comprehended. Alcohol degeneration is the sequence. The alcohol in the cholesterin exists in exactly sufficient proportion to determine normal nerve health. Change that normal proportion by the excessive use of alcohol, and the relationship which the unstable compounds normally preserve is overthrown, degeneration ensues, and we then have the disorder commonly known as alcoholism.

Now, what measures shall we pursue to cure this habit, or habits, I may say, for these remarks also apply to the various drug habits? The answer seems obvious. In the first place, measures must be taken which arrest degeneration and have such a selective influence on the nerve substance as to restore the normal balance of the elements named above. In treating these cases my first duty has been to withdraw from the habitue, quickly, but painlessly, the liquor or drug to which he or she has been addicted. This can be very easily done by subjecting the patient to a peaceful slumber of from thirty-six to forty-eight hours. Before this stage of the treatment, however, the patient's entire intestinal tract should be thoroughly and completely emptied, after which he or she should receive a Turkish bath, and after that a good, gentle scrubbing with a pure, non-irritating soap and water. The patient is now ready to be placed in bed in a darkened room, which should be in a quiet part of the house.

While the patient remains in this state of quiet repose the poisonous drug or liquor should be thoroughly eliminated by every means known to medical science; as, for instance, by the skin, liver and intestines, lungs, and kidneys. During this period the patient should be aroused at frequent intervals and induced to drink milk, egg-noggs, or other nourishing liquids; this should be done regularly, for the patient can at all times during the treatment be awakened for a sufficient length of time to receive nourishment; he immediately afterward drops back into a restful sleep.

After the poisons have been thoroughly eliminated from the patient's system, he should be allowed to awaken of his own accord. The patient should remain quietly in bed for a day or two after awakening. He should then be placed upon a rapid and effective tonic treatment and allowed plenty of fresh air, together with a mild form of exercise. By this time he will have developed a ravenous appetite, and this should be encouraged as much as possible, for the reason that the more food is consumed, the less medicine will be required. Too much medication must be strictly avoided, especially so drugs of a narcotic nature. Large doses of strychnine, and drugs of a similar class, should also be avoided, for they have a tendency to aggravate the already over-wrought condition of the nerves, through their irritating action on the spinal cord.

Medicines of nerve-tissue-building properties, should be used in very large and frequent doses, rather than powerful stimulants, for the latter frequently cause more harm than good. With a little patience on the part of the patient, and some coaxing, nature will, in a comparatively brief space of time, restore the normal condition.

By placing patients under heavy and frequent doses of one or more of the recognized nerve-tissue builders, I have observed that they impart tone and vigor to the entire nervous system, improve the arrested or defective metabolic changes needful for repair and assimilation, assist the restrictive power of the will against the opposing influence of the morbid propensity, and restore healthy functional activity to all the organs. In case a heart stimulant should be required, liberal doses of sparteine sulphate can be used with perfect safety, and with no danger of bad after-effects.

To deal successfully with those who are addicted to alcohol or the various drugs, and who therefore suffer from the above-mentioned consequences, and to meet the inroads of these habits, requires tact, discretion, and exceptional determination; tact in addressing the patient, discretion in discussing his or her disorder, and a determination which involves a moral supervision and control. Such means should be resorted to as proper isolation, removal from temptation, conversion of appetite, improved hygiene, and proper mental recreation; and in order to provide such conditions, it can readily be seen that treatment in private sanatoria is the ideal treatment in all such cases.

In conclusion, I wish to add that my personal experience with the various preparations of ergot in the treatment of addictions has been that they have been most unsatisfactory. As a curative agent for addictions, ergot is a failure; as an aid in restoring the vascular system to a normal condition after the addiction has been cured, I have found ergot to be of material benefit. I mention these few facts in reference to ergot for the reason that so much seems to have been written lately in its favor as a curative agent in addictions, especially in morphinism.

In regard to alcohol, my statements in this paper must not be misconstrued as directed toward the entire condemnation and abolition of alcohol as a therapeutic agent. I have merely attempted to explain my own theory of morbid conditions incident to its protracted use.

10 West Avenue.

The College of Physicians of Philadelphia.—It is reported that this society is about to begin work on a new building to cost approximately $250,000. This sum will be realized very nearly by the sale of the present building and of the lot on which it stands.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51, FIFTH AVENUE.

New York, August 20, 1904.

THE CARDIAC AND VASCULAR COMPLICATIONS OF TYPHOID FEVER.

THE complications of typhoid fever, in common with other infectious diseases, are exceedingly varied. Some of these are due directly to the intestinal lesions—for example, the intestinal hemorrhage and perforation and peritonitis—while others are due in part to the causative infectious agent, and in part to the resulting intoxication. Among the latter may be mentioned various inflammatory disorders involving muscles, bones, serous membranes, and visceral structures. Endocarditis and arterial and venous thrombosis are by no means uncommon in the course of typhoid fever, and alterations in the myocardium are rarely wanting. It would, therefore, seem likely that this disease may be considered as one of the many causes of cardiovascular sclerosis. With the object of establishing the accuracy or otherwise of such a view, Dr. W. S. Thayer (*American Journal of the Medical Sciences*) undertook a study of the heart and blood-vessels in 183 of the 1,400 individuals that had at some time within the previous fourteen years been treated for typhoid fever in the wards of the Johns Hopkins Hospital. As a result he found the average systolic blood-pressure appreciably higher than in control healthy individuals. This higher average of blood-pressure was constant for every decade of life. In many instances the blood-pressure in the cases of earlier typhoid fever exceeded appreciably the limits of what is usually regarded as normal. The radial arteries in these cases were palpable in a proportion nearly three times as great as that observed in controls—supposedly healthy individuals who had never had typhoid fever. The average size of the heart was larger among the cases of earlier typhoid fever at the late examination than at the time of admission to the hospital. This difference existed also when the cases were classed according to age by decades. Cardiac murmurs were heard with considerably greater frequency among the cases of earlier typhoid, and in the same cases during the attacks, than in individuals who had not had typhoid fever. In eight cases in which, on discharge from the hospital, the heart was considered normal, subsequent examination disclosed the existence of hypertrophy with mitral insufficiency. In one case there was possible mitral stenosis, in one aortic insufficiency, in one general arteriosclerosis with hypertension. In one case an aortic diastolic murmur was present four months after discharge, but this had disappeared five months later. Those patients in whom the pulse, during the course of the disease, was remarkably rapid or irregular exhibited in general, on later examination, a blood-pressure above the average common for the cases of earlier typhoid fever. In other respects, however, their condition differed but little from the general run of cases. Those cases in which a systolic murmur, at the apex of the heart, was observed during the attack exhibited later an increase in the blood-pressure and in the size of the heart, as compared both with the mean of the observations made upon the same cases on admission to the hospital and with the general average for the cases of earlier typhoid fever. Nearly one-quarter of the cases in which, during the attack, systolic apical murmurs were detected exhibited on later examination evidences of organic heart disease. Indeed, the majority of all the cases of organic cardiac lesions among the 183 cases of earlier typhoid fever were derived from this small group of thirty-one cases.

The evidence presented furnishes a further reason, if such were needed, for the institution of any and all legitimate measures directed to the prophylaxis of typhoid fever, and in the event of its development for the adoption of all precautions and therapeutic procedures calculated to avert cardiovascular complications.

THE ACTION OF SALINE PURGATIVES IN RABBITS AND THE COUNTERACTION OF THEIR EFFECT BY CALCIUM.

A PUBLICATION by the University of California on this subject, written by Dr. John Bruce MacCullum, has recently been issued. Schmiedeberg, in his attempt to explain the action of saline purgatives, states that these salts are absorbed with difficulty and hence reach the lower part of the intestine unchanged.

Wallace and Cushny support this view and add that the absorption of fluids from the intestine is retarded, especially by the salts of those acids which tend to form insoluble salts with calcium. Loeb, while not denying the possibility of the inhibiting action of the saline purgatives on absorption, states that these salts are identical with those which produce contact irritability, muscular twitchings, and hypersensitiveness of the nervous system. Further, he suggests that the increased peristalsis may be due to an increase in the irritability of the nerves and muscles of the intestines.

MacCullum, in order to decide this question, made a series of experiments on rabbits, testing the action of a number of salts, and reached the following conclusions:

(1) In general, the saline purgatives act not only when introduced into the intestine, but also when injected, subcutaneously or intravenously. (2) The intensity of their action is greatest with barium chloride and decreases approximately in the following order: barium chloride, sodium citrate, fluoride, sulphate, tartrate, oxalate, and phosphate. (3) The purgative action of these salts is caused, first, by an increase in peristalsis, and, second, by increased secretion of fluid into the intestine, both of which can be directly observed. (4) Although the writer has not specially studied the secretion of other glands, he has noticed that in a number of cases an increased flow of saliva and urine occurred

when these salts were introduced into the body. (5) Intravenous injection of 1 to 2 c.c. $\frac{m}{2}$ solution of these salts increased peristalsis within one minute. When introduced into the intestine, it takes ten to fifteen minutes, and five times the amount to produce an equal effect. (6) This seems to indicate that even when these salts are introduced into the intestine, they must be absorbed into the blood before they can produce their purgative effect, and that they affect the intestine by increasing the irritability of the nerves and muscles, as Loeb has suggested. Their action in producing less solid fæces is not due to the prevention of the absorption of fluids from the intestine, but to the production of an increased secretion of fluid into the intestine. (7) By the continued administration of small doses of sodium citrate, a chronic condition of hypersensitiveness of the nervous system may be brought about in rabbits, which persists for a considerable time after the drug is discontinued. (8) By the injection of solutions of calcium chloride, the peristalsis caused by these salts can be entirely inhibited. (9) There is a perfect analogy between these actions and the production and suppression of muscular twitchings and nervous hypersensitiveness. (10) The administration of calcium is, therefore, rational, especially in those cases of diarrhœa in human beings which accompany hysteria or nervous excitability of any sort.

Dr. MacCullum says that while it is difficult to disprove Schmiedeberg's theory, that the absorption of fluids from the intestine is retarded by saline purgatives, it is certain that the main factor in the production of fluid or less solid fæces is the increased secretion of fluid into the intestine. Referring to the possibility of administering purgatives to human beings subcutaneously or intravenously, the writer is of the opinion that although in general such methods would be contraindicated, certain cases might arise in which it would be of distinct advantage. The present experiments seem to indicate that subcutaneous or intravenous administration of some of the salts, especially sodium citrate or sulphate, might be safely resorted to. Dr. MacCullum, however, utters a warning against giving barium chloride or magnesium sulphate in this way.

The Present Status of Clinical Osmology.

The appearance of several important works on this subject makes it pertinent to review briefly the progress of this branch of physical chemistry in medicine. H. Zikel (*Zentralblatt für innere Medizin*, June 25, 1904) believes that to A. v. Koranyi must be given the credit for first applying the scientific facts of osmology to clinical medicine. The pectoscope, as suggested and recommended by Zikel, has now been adopted as the most ready means of determining the freezing point, which in any fluid, is proportional to the osmotic pressure of the substances held in solution. The principles of the clinical application of cryoscopy depend entirely and solely on the laws of osmotic equilibrium in the organism. The average figure in a normal person, as measured by the freezing point of the blood, may be stated to be 0.56°C. The renal parenchyma has been found to exert the greatest influence on the molecular concentration of the blood, this organ being succeeded in importance by the liver and then the lungs. Diseases of these organs are therefore accompanied by well-marked disturbances in osmosis.

The freezing point of urine is determined from a specimen taken in the early morning before any food is eaten. By means of the administration of salt, the function of concentration may then be determined, and by the ingestion of water, the powers of dilution possessed by the kidneys. In the presence of a parenchymatous nephritis both functions are inhibited, in contrast to the almost normal behavior seen in the case of an interstitial nephritis.

Hamburger, whose textbook has just been completed, lays particular stress on the value of osmology in cardiac and renal disease, and claims that the cryoscopy is the only reliable and accurate method for ascertaining any inhibition of the circulatory stream. In certain patients affected with cardiac disease, the blood current may be perfectly normal when at rest, but may be markedly affected by exertions which would have no effect whatever in a healthy individual. Koranyi has suggested that the most sensitive method for estimating the degree of interference with the blood current, is to determine the molecular concentration and the sodium chloride content of the urine. This suggestion possesses considerable therapeutic value, as the patient's manner of life may be adjusted to the functionating powers of the heart, measured as just indicated. So long as the circulatory disturbances subside, the dyspnœa is reduced and a return to the normal is secured by rest, a permanent dilatation need not be feared.

Of great importance in renal surgery is the observation of Kümmel that the functionating powers of the individual kidneys may be exactly determined. In this way, when nephrectomy is contemplated, it is possible to know in advance whether the remaining kidney can fulfil the double function enjoined upon it. In this instance, cryoscopy is certainly of greater importance than either the methylene blue or the phloridzin tests.

The field for osmology is not restricted to any one organ but includes the entire human organism. It is still in the infancy of its development but already occupies an important position in clinical medicine.

Water Shortage in Southern California.

The scarcity of water throughout southern California has been this summer no greater, perhaps, than during former summers, but it has given more than ordinary inconvenience. In Los Angeles, where the public improvements for several years have been severely taxed to keep up with the rapidly increasing population, it became necessary to warn the people against waste of water. It was then shown that the average consumption of water in the city amounted to more than forty-six gallons a day for each person, or about three times the average quantity said to be consumed in New York City. The principal waste, if it should be regarded as waste, arose from the use of automatic sprinklers, without which it would be almost impossible to preserve the vegetation which adds so greatly to the beauty of the city. Happily the supply is sufficient to preclude the possibility of a water famine severe enough to menace health. The same difficulties are being experienced in the cities south of Los Angeles, particularly in Santa Ana and San Diego, and in them the supply is more precarious.

The water conditions in San Diego are altogether peculiar to the place. It is a fact that causes not a little astonishment to visitors that the San Diego River, the principal source of the water supply for the city, flows "bottom side up." In other words, the broad river bed is as dry as the proverbial chip, and it has been so for a great many years. It is only necessary to sink large pipes into the gravel

and boulders to a depth of thirty-five feet in order to reach an almost inexhaustible quantity of water. Less than a dozen wells of this character are required to supply the city with from two to three millions of gallons of water daily. But the entire water plant is only a temporary makeshift, liable to fail at any time. During a greater part of the present summer the supply has been so limited, or, as some assert, the facilities for its pumping have been so neglected, that the higher parts of the city have been left without water almost daily for from eight to twenty hours at a time. Fortunately neither fire nor pestilence has yet taken advantage of the opportunities afforded, and the people meekly submit to the inertia of the office holders. It is conceded that a caisson sunk to the depth of fifty or sixty feet would afford an inexhaustible supply of water and with less expense than obtains with the present system. But the San Diegan is averse to undertaking anything that Providence may do for him, and constantly lives in hope of a better rainfall next winter.

One of San Diego's wealthy benefactors has decided to build a flume to conduct water from a source many miles back in the mountains. The water will be of much better quality than the present supply and more plentiful, but it will require several years to complete the construction.

The Habits and Diet of the Japanese Soldier.

It is a remarkable circumstance that the Japanese troops in the field have not been attacked by an epidemic of typhoid fever, cholera, or plague, considering the conditions under which they live. The Japanese soldiers are crowded into the houses of the country, which are small and ill-ventilated. The Koreans and Manchurians know nothing of sanitation and care less, and it is certain that if Caucasian troops had undergone an ordeal similar to that to which the Japanese soldiers have been subjected during the past few months, a pestilential epidemic would have been the result and deaths would have occurred by the thousands. The Manchuria correspondent of *Leslie's Weekly* thinks that the Japanese are less susceptible to the attacks of disease germs than are Caucasians, but is of the opinion that there are other reasons which explain their freedom from disease. To begin with, their diet is extremely plain and simple, consisting chiefly of rice, salt fish, and unsweetened tea. Other civilized armies, on the contrary, when on active service, eat highly concentrated and heating foods. They drink large quantities of strong coffee, and gorge themselves with hardtack, bacon, canned beef, and jam, bringing on a whole train of stomachic and intestinal troubles and lowering the system generally. The men thereby lay themselves open to the danger of contracting various diseases. Again, the Japanese soldier always drinks boiled water or a very weak concoction of plain hot green tea. Unlike American and British soldiers, upon taking possession of a town the Japanese fighting man does not proceed to drink to excess; he is temperate to a degree, and indulges in no alcoholic stimulant but his mildly alcoholic sake. Thus by careful diet his body is in good physicial condition and fitted to resist the onslaughts of disease.

The Zittmann Treatment of Malignant Syphilis.

Ordinarily the suppression of symptoms in syphilis is not difficult. But now and then so-called malignant cases arise in which mercury and iodide of potassium do no good, the disease runs a most rapid course, the lesions break out all over the body, and in the space of a few weeks terrible destruction of tissue may occur, with the result of most unsightly deformities, and frequently a fatal outcome, either from the development of gummata in the vital organs, or from exhaustion following ulcerative processes. It is precisely in these cases that the advocates of the well-known Zittmann treatment claim that it works most beneficially and that it deserves to be much better known than it is. The underlying principle is the expulsion of the poison by diaphoresis and purgation. In many cases in which the ravages have been most extensive, with great destruction of tissue, a fortnight's treatment not only completely arrests the progress of the disease but brings about rapid healing and cicatrization. Marked benefit also results to tertiary nerve lesions.

The evening before the treatment is commenced the patient receives 2 grs. of calomel, 5 grs. of compound extract of colocynth, and 2 grs. of extract of hyoscyamus. The remaining materia medica consists of two decoctions. The first consists of sarsaparilla root 4 oz., aniseed and fennelseed each 500 grs., senna leaves 1 oz., and licorice root 4 oz.; these are bruised and added to 4 gallons of water, together with 80 grs. each of white sugar, alum sulphate, and calomel, and 20 grs. of the red sulphide of mercury enclosed in a linen bag; the water is then boiled down gently to one gallon. The dregs of this are then put into 3 gallons of water, with 2 oz. of sarsaparilla root, and 1 oz. each of lemon peel, cardamom seed, and licorice root, and boiled down to one gallon. This is the decoction No. 2.

The morning after taking the two pills, the patient drinks half a pint of hot decoction No. 1, at 9, 10, 11, and 12; and in the evening he drinks half a pint of cold decoction No. 2, at 3, 4, 5, and 6. He is kept in bed except for one hour's sitting up in the evening. This routine is repeated for four days. On the fifth day the patient takes a hot bath and is allowed to dress. In the evening two pills are administered (as on the first night), and the next day the treatment is resumed. This course is followed out for fifteen days, after which it is discontinued.

Though one might, from its degree of complexity, be inclined to suspect that the essentials of the method have not yet been sifted out very well, still Sir Alfred Cooper, who writes on it in the London *Practitioner* for July, remarks that the way in which bad cases will clear up under it when all other treatments have failed, is astonishing.

Fruit and Filth.

An article bearing the above title is contributed by a correspondent to the *Lancet* of July 16. The question of fruit as a means of conveying infection has been frequently raised, and although various precautionary measures have been suggested and in some places carried into effect, the matter is still in an unsatisfactory state. Much of the fruit which is displayed for sale on open-air stalls and push carts provides a most convenient receptacle for dirt and gathers a variety of germs, some of which are distinctly prejudicial to health. The correspondent of the *Lancet*, after drawing attention to the disgraceful sanitary conditions which prevail among the majority of those who gather fruit in England, proceeds to describe the process of converting fruit into jam practised in certain factories. "As the fruit," says the writer, "was delivered from railway wagons and the firm's own vans, it was handed over to dirty old women to pick off the stalks and again went through a large amount of unsavory handling.

Then part of the fruit was made straight into jam by boiling it in steam jacketed pans with sugar. . . . The workers in the factory were certainly a little cleaner than the fruit pickers, but were still of a very miserable, unwashed description. I feel sure that anyone who had seen the way in which fruit is handled would require a warranty from the jam maker that the fruit had been picked by cleanly people and made into jam by decent folk." It is certain that the methods of both fruit picking and of jam making in use in Great Britain need alteration.

The picking of fruit in this country and its packing for the market are much more cleanly operations, at least on the large fruit farms of the West and South. As to the menace to health, however, of fruit exposed on stalls and pushcarts, enough is known to render it obvious to any ordinarily observant person that the custom is dangerous. In New York, for instance, dust is always being blown hither and thither, and fruit exposed receives a proportion of the particles which are always floating in the air. The habits of a majority of the out-of-door fruit vendors are not cleanly, and sufficient care is not taken to protect their wares from contamination. The matter is one which may be suggested as worthy of the attention of boards of health throughout the country.

Eyestrain Looking Up.

A new disease added to the long list of those asserted by the talented author of "Biographic Clinics" to be due to eyestrain is alcohol addiction. At a meeting of opticians at Milwaukee on Wednesday of last week, a Chicago refractionist reported a case of chronic alcoholism cured by eyeglasses. The speaker took the obvious ground that the craving for alcoholic stimulation was a nervous affection, and he had found, he said, in a long series of ocular examinations, that inebriates often suffer from anomalies of refraction and other producers of eyestrain. Such being the case, the natural corollary follows that spectacles will cure inebriety. The reasoning is as profound and as sound as a good deal of that used by many of the extreme advocates of the eyestrain theory, and no doubt we shall soon have the inebriate looking through other glasses than those he must tip up to make transparent.

Dr. Osler Goes to Oxford.—The announcement is made by cable from London that, with the approval of King Edward, Dr. William Osler, now of the Johns Hopkins University, Baltimore, has been appointed Regius professor of medicine at the University of Oxford, in succession to Sir John Burdon-Sanderson. This news will be received with deep regret by a host of friends and admirers of Dr. Osler in this country, who have long looked on him as one of the leaders in American medical thought. Dr. Osler has passed all his professional life as a teacher of medicine, a vocation for which he is eminently qualified by his broad culture, profound medical learning, and an inborn gift of expression. He was born in Tecumseh, Ontario, in 1849, and was graduated in medicine from McGill University, Montreal, in 1872. For ten years, from 1874 to 1884, he was professor of the institutes of medicine at McGill, from 1884 to 1889 he was professor of clinical medicine at the University of Pennsylvania, Philadelphia, and since 1889 he has held the chair of medicine at the Johns Hopkins University, Baltimore. We beg to offer our congratulations to the new Regius professor of medicine at Oxford, and at the same time to send anticipatory greetings to Sir William Osler, Bart. The Oxford School of Medicine is also and especially to be congratulated.

News of the Week.

Medical Interest in Our Dispute with Turkey.—One of the chief grievances of this country against Turkey, a settlement of which was forced only by sending some warships to Smyrna, was that the most favored nation treatment was not accorded the American College in Beirut. Under the Mytilene agreement of 1901 the French Medical School at Beirut enjoyed privileges denied to the American Protestant Medical College at the same place. Graduates of the American institution were not allowed to practise their profession freely, and the faculty was handicapped by regulations that impaired its usefulness. To diplomatic representation the Porte for a long time turned a deaf ear, and it was not until the day before the American ships arrived at Smyrna that the Sultan saw his way clear to do what he had to do. He then agreed to grant most favored nation treatment to the Beirut and other American schools, and also to pay up what he owed the United States.

St. Louis Society for the Prevention of Tuberculosis.—This society, the aims of which are expressed in its title, has recently been organized. The plan of work will consist in giving wide publicity to the fact that the mortality from tuberculosis in St. Louis is steadily increasing, and that the measures of prophylaxis now obtaining in Philadelphia and New York, if applied to St. Louis, would mean a saving of 40,000 lives in the present generation; and in conducting a campaign of education by medical tracts, personal instruction in hygienic living, and public lectures and stereoptican demonstrations to the children of the public schools. A concerted effort will be made to secure the enforcement of the anti-spitting law. Tenement-house inspections will be made, and statistics will be collected and published concerning the tuberculosis centers in the city and the location of infected houses. The officers of the society are: *President*, Mr. F. E. Eaton; *Secretary*, Mr. G. A. Blickhahn; *Treasurer*, Mr. J. W. Lambert. The Medical Committee is composed of Dr. William Porter, chairman; Drs. H. Wheeler Bond, W. J. Harris, George Homan, Charles H. Hughes, Harry W. Lyman, Wm. A. McCandless, W. G. Moore, Jesse S. Myer, E. W. Saunders, John H. Simon, Jos. Spiegelhalter, Justin Steer, James H. Tanquary, George M. Tuttle, and E. J. Goodwin.

The Validity of an Agreement Not to Practise in a Given Locality.—A physician of Atlantic City has filed a bill in the Chancery Court which asks that another physician of the same place be required to show cause September 6 why he should not be enjoined from further practising medicine in Atlantic City. The bill sets forth that the complainant has been practising medicine in Atlantic City for more than twenty five years, and that during the last fifteen years his practice has been so extensive that he required the services of an assistant. During these fifteen years he has had numerous assistants, and he states that it was his invariable custom to require these assistants, in entering upon their duties, to sign an agreement by the terms of which they deprived themselves of the right to practise medicine in Atlantic City after severing their connection with him. His object in requiring this agreement was, he says, that his assistants might not ingratiate themselves in the favor of his patients, and thus take his practice away from him. In March, 1901, he employed an assistant at $40 a month and 35 per cent. of the money that he collected for his personal services, and the same agreement was made regarding future practice in Atlantic

City. But the former assistant is now practising independently in violation of this agreement, and so an injunction is asked for.

A Commission to Study Pneumonia.—In response to the request of Dr. Darlington, Health Commissioner of this city, the Board of Estimate of New York has appropriated $10,000 to meet the expenses of a commission to investigate the causes and prevention of pneumonia. This commission will consist of Drs. Frank Billings of Chicago, John H. Musser of Philadelphia, Theobald Smith of Boston, William Osler and Wm. H. Welch of Baltimore, and Edwárd G. Janeway, L. Emmet Holt, and T. Mitchell Prudden of New York City.

Chicago Mortality of the Week.—Of the 473 deaths for the week ended August 6, acute intestinal diseases caused 120; consumption, 58; violence, 44; heart disease, 34; Bright's disease, 33, and pneumonia, 27. The annual death rate per 1,000 was 12.78, which compares very favorably with 14.29, the rate for the corresponding week last year.

New Swedish Hospital in Chicago.—On July 20, articles of incorporation were issued for the Washington Park Hospital, a Swedish hospital which is to be erected near Washington Park, Chicago. At present the hospital occupies a building at Sixtieth St. and Vincennes Ave., and has accommodation for thirty patients.

Hygienic Backsliding in Cuba.—Many of the cities of the eastern part of Cuba are rapidly becoming as filthy as they were under Spanish rule, the authorities refusing to clean the streets, on the ground that no money has been appropriated for the purpose. The United States Government has repeatedly directed the attention of the Cuban Government to the sanitary menace of this neglected condition of the cities of Eastern Cuba, and these representations have now resulted in a decision by President Palma to reform the system of municipal tax collections and to have new assessments made throughout the island. The result of this action will, it is expected, be an increase in the municipal revenues, and then if the municipal authorities still persist in their neglect measures will be taken to remove them.

Smallpox in Zion.—Dowie, the "divine healer," has a job on his hands now in the cure by prayer of a number of smallpox cases. The patients have been isolated by the health authorities, but are not allowed by their ruler to receive medical attention. Dr. Herman Spalding of the Chicago Health Department, a deputy State health inspector, visited the city a few days ago and examined the cases there. He found sixteen cases of smallpox, but pronounced them a mild form of the disease. None of the patients has been vaccinated, however, as vaccination is not permitted in Zion City.

"Academies for Practical Medicine" in Germany.—Minkowski describes, in a recent issue of the *Berliner klinische Wochenschrift*, an institution which is to be opened in Cologne in October, and which is the first of a number planned for other German cities. The object of these institutions is to furnish practical post-graduate instruction to physicians, and the idea is acknowledged to be based on the American post-graduate schools, the Post-graduate Medical School of New York being specifically mentioned. It is not intended to interfere with the scope of the regular undergraduate schools, but merely to supplement them, and to render available for study much clinical material which would otherwise serve no useful purpose. The public hospitals of Cologne have lately been very much enlarged and extended, and their departmental chiefs will, for the present, conduct the post-graduate instruction, with the assistance of a number of specialists. A union with the University of Bonn is also proposed, and several professors from the latter institution have been designated to serve on the faculty.

Sir Frederic Bateman, who died in Norwich, England, on August 10, was an honorary member of the New York Neurological Society. He was born in 1824, and received his degree of M.D. at Aberdeen in 1850. He wrote a number of essays on subjects connected with the function of speech, his work on "Aphasia and the Localization of Speech" gaining for him the Alvarenga prize of the Paris Academy of Medicine. He was knighted in 1892.

A Sewer System for Los Angeles.—The health officer of Los Angeles, in a recent report, shows that several districts, comprising 40 per cent. of the area of the city, are not provided with sewers. In these districts, however, the rules regulating the use of cesspools and vaults are very rigid and have been strictly enforced by the Board of Health. While there has not been any great excess of illness in these districts, it is shown that nearly all cases of typhoid fever, diphtheria, and other more common infections occurring in the city have been limited to them. Fortunately work is to begin immediately upon an extensive sewer system and there is a fund of $1,000,000 available for its construction.

The Fourth Pan-American Medical Congress, which was to have convened the latter part of December of this year at Panama, has been postponed until the first week in January. This was done at the request of many physicians who wished to take part in the congress, but desired to be at home with their families during the Christmas holidays. The delegates from this side of the continent will therefore leave on Tuesday, December 27, if they go down from New York by the regular Pacific Mail steamer, or they may go by way of New Orleans or Jamaica. The congress will be held from the fourth to the seventh of January. The officers of the congress appointed by President Amador of the Republic of Panama are: Dr. Julio Icaza, Dr. Ciro Uriola, Dr. J. Calve, Dr. Carlos Cooks, Panamanians; Dr. Gorgas, chief of the Panama Canal Sanitary Commission, Drs. Carter and Ross, Americans; Dr. Manuel Corales, Cuban; Dr. M. Stern, English, and Dr. Oduber, Dutch. This congress bids fair to be the most successful Pan-American Medical Congress that has ever been held, on account of the central situation of Panama and its easy approach from both sides of North America, Mexico, and the Central-American Republics, as well as from the countries on the north and west sides of South America. There will be four sections at this congress, viz., Surgery, Medicine, Hygiene, and the Specialties.

Dr. H. Stow Garlick of Cincinnati has been appointed surgeon of Battery B., O. N. G., at Cincinnati. He was formerly on the Medical staff of the First Regiment. He succeeds Dr. Rothert, resigned.

Prevention of Street Car Accidents.—A Coroner's jury in St. Louis has recommended that a new law be enacted compelling all cars to stop on near crossings, and not permitting one car to pass another which passengers may be entering or leaving, or but very recently have left or entered. If enforced, it will prevent injury and death caused by persons passing behind one car and in front of another going in an opposite direction. The recommendation was prompted by the killing of two women who had alighted from one car and passed over to the tracks on the opposite side and in front of a car going at a

high rate of speed. One of the women was instantly killed and the other died shortly after being taken to the hospital. The jury held the motorman and the officials of the company culpable for the death of the victims.

Number of Physicians in New York City.—The "Medical Directory of the City of New York," in the edition for 1904, just issued, contains the names of 5,909 practitioners in Greater New York. These are distributed as follows: Manhattan and The Bronx, 4,211; Brooklyn, 1,519; Queens, 121; Richmond, 58.

New Hospital Accommodation in Chicago.—The Sisters of St. Anne have completely isolated one wing of their sanatorium for consumptives at Forty-ninth and Thomas streets, Chicago. They have fitted up operating and dressing rooms, and are now taking general medical and surgical cases. The hospital building was erected only a few months ago, and is equipped with all modern appliances

Health Board Troubles in Brooklyn.—Dr. Patrick J. Murray, since January 1 assistant sanitary superintendent for Brooklyn, was removed recently by the Health Commissioner. In explanation of the removal Dr. Darlington has stated that the conduct of the work of the Health Department in the Borough of Brooklyn has been unsatisfactory to the board, and the inspectors have made an exhaustive investigation. As a result of their report the Health Board decided upon Dr. Murray's removal. Sanitary Superintendent Roberts has charge of the department's affairs in Brooklyn pending the appointment of a new assistant. The newspapers attribute the removal to political causes. Dr. Murray being a follower of the anti-Tammany leader in Brooklyn.

Civil Service Examinations.—The New York State Civil Service Commission announces that general examinations will be held on September 10 for various positions, including those of apothecaries in State hospitals and institutions, physicians both regular and homœopathic in State hospitals and institutions, and trained nurses in State hospitals and institutions. Applications for these examinations must be made on or before September 3. Full particulars of the examinations and application blanks may be obtained by addressing the Chief Examiner of the Commission at Albany.

Rocky Mountain Interstate Medical Association.—The next meeting of this society will be held at Denver on September 6 and 7, under the presidency of Dr. H. D. Niles of Utah, Nev. The corresponding secretary is Dr. George A. Moleen, Mack Block, Denver, Colo.

The Medical Society of the Missouri Valley will hold its seventeenth annual meeting at Council Bluffs, Iowa, on August 25 and 26, under the presidency of Dr. A. D. Wilkinson of Lincoln, Neb. The secretary is Dr. Charles Wood Farrett of St. Joseph, Mo.

Pennsylvania State Medical Examinations.—Of 379 applicants for license to practise medicine in the State of Pennsylvania 306 passed the examinations held recently, while 73 failed.

Bequests to Hospitals.—By the will of Cornelia Thompson the sum of $10,000 has been devised to the Presbyterian Hospital of Philadelphia, for the endowment of two free beds, and the sum of $5,000 to the Children's Hospital.

Deportation of a Leper.—A leprous Mexican boy, who was discovered in the vicinity of Colton, San Barnardino County, Cal., nearly six months ago, has been deported. He had been in the vicinity for about a year. The father has been placed under arrest, charged with violating the quarantine regulations, as if to attone for the carelessness of the officers who have disregarded the case so long.

Concealment of Cases of Contagious Disease.—Forty cases of diphtheria have occurred in Riverside, Cal., during the past year, and it is alleged that the number might have been less if the public had been warned. There is a tendency throughout the State to conceal all conditions that might keep away the tourists, who are the fat of the land; but the mercenary spirit seldom reaches the medical profession. The Chinese physicians in some places have been accused of treating diphtheria under the diagnosis of "stomach trouble" and neglecting to report the cases to the authorities.

Suture of the Heart.—The rare operation of suturing an incised wound of the heart was performed by Dr. A. M. Smith, at Los Angeles, Cal., on July 28. Four days afterward the patient was in good condition.

Dr. Walter Lindley, editor of the *Southern California Practitioner*, has recently been elected Dean of the Medical College of the University of Southern California. This Los Angeles school is now entering its twentieth session. Dr. Lindley was one of the organizers of the school, and is Professor of Gynecology in the institution.

Obituary Notes.—Dr. Joseph Wiener died in this city on August 11, of disease of the heart, at the age of seventy-six years. He was born in Bohemia, April 5, 1828, and came to this city in 1849. For thirty-five years he was actively engaged in the practice of medicine here, during a large part of this time in association with the late Dr. William Detmold. He was one of the founders of the department of pathology in the College of Physicians and Surgeons. Dr. Wiener retired from practice more than twenty years ago. Throughout his entire life he was an enthusiastic lover and collector of objects of art and was a member and patron of the Metropolitan Museum of Art and of the Museum of Natural History. He was also a member of the Geographical Society, the Academy of Sciences, the Numismatical Society, the Symphony Society, the Oratorio Society, and various other scientific and literary organizations. He was one of the founders of the Palette Art Club. In 1885 he presented a statue of Washington Irving, now in one of the public parks, to the city.

Dr. John Thurman Parker died August 13 from Bright's disease, at his residence in this city. He was born in Thurman, Warren County, in 1837, and came to New York thirty years ago. He served as an assistant surgeon with the 169th New York in the Civil War, and was one of the physicians who attended the inmates of Libby Prison when they were liberated.

Dr. Lyndhurst F. Dodge died suddenly of disease of the heart at his home in Rouse's Point on August 12. He was a graduate of the Albany Medical College in the class of 1862.

Dr. William D. Spore of St. Louis died at the Mullanphy Hospital in that city on August 10. He was sixty-three years old and was the oldest living graduate of the Missouri Medical College. He had traveled in every part of the world, and the greater part of his life was spent aboard ship. He had been purser and surgeon on a Brazilian steamship line, and had been connected with the White Star, the Red Star, and the Cunard lines, his last service being on the American Line steamship *Paris*.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE MEDICAL MEETING AT OXFORD—ASYLUMS BOARD—SMALLPOX —DEATH OF SIR JOHN SIMON, K.C.B., F.R.S., ETC.

LONDON, July 29, 1904.

MEDICAL interest this week has centered in Oxford, where the innumerable objects of interest might well deprive the scientific portion of the British medical meeting of full attendance. As if the usual delights of Oxford were not enough, a long series of entertainments was provided. Nevertheless, a good deal of practical work has been done in the sections, as your reports will show.

The opening service at the Cathedral was attended by a large number of visitors. Many members who went met at the Town Hall and marched in procession, wearing, by request, their academical robes. Perhaps in an ancient university city this may be considered an appropriate display. The variety of capes and gowns collected from so many universities as these members represented added vivid color to the scene, which I am told was exceedingly picturesque, but marred by heavy rain. The weather was unpropitious at later functions and my correspondents were rather lugubrious over it. One says the President's reception in the lovely gardens of Wadham College was spoiled by the heavy downpour, though the fine trees afforded some shelter and many seemed to enjoy themselves. It was, however, necessary to transfer to the Town Hall the fencing exhibition which was intended to be one of the principal items of amusement.

A very useful Guide to Oxford was presented to members, and in the daily journal of the Association was inserted an account of some of the most inviting bicycle rides in the neighborhood.

The annual report of the Asylums Board is just out, from which I notice no less than fifty-one establishments are owned by the board, viz., seventeen hospitals for infectious cases, five asylums for imbeciles, a training ship, thirteen homes or schools for certain classes of children, and eight ambulance stations. During the year, 21,925 patients passed through the fever hospitals and 359 through the smallpox hospitals. The expenditure for the year was £1,123,130.

The County Council has made chickenpox notifiable until November, and engaged an expert who will advise any practitioner as to a doubtful case of smallpox, without cost to those who call him in.

Sir John Simon, K.C.B., died on Saturday. He had reached the advanced age of eighty-eight. Of course he had retired for some years. He resigned the office of Medical Officer to the Local Government Board, in which he had done so much good sanitary work in 1876. He was also Medical Officer of the Privy Council, and before that to the old General Board of Health. It was in these offices that he attained the reputation of the leading sanitarian. His annual reports formed a most valuable series of blue books on public health. He not only led the sanitary work of the country but may be regarded as the founder of school of sanitarians who have carried on the work since his retirement. He seemed always to make most admirable selections of men to assist him in the work and to undertake any inquiries he wanted made. His acknowledged position at the head of English sanitarians largely overshadowed his reputation as a surgeon, at any rate with the younger generation. But he was a surgeon of no little repute. In 1844 he was one of the elected Fellows of the College of Surgeons, and from 1853 to 1876 was surgeon to St. Thomas' Hospital, becoming consulting surgeon in the latter year. Earlier still—in 1847—he became lecturer on pathology at the hospital, an office he held until 1870. Of course he joined the Pathological Society; of that he was president from 1866 to 1868. He reached the presidency of the College of Surgeons in 1878 and the next year the vice-presidency of the Royal Society, of which he had been elected a Fellow in 1845. His sanitary work began when the post of Medical Officer of Health to the city was created in 1848, and he was elected to fill it and held the office until nominated by the government to the Board of Health. He served as crown member of the General Medical Council from 1879 to 1895. He was decorated C.B. in 1876 and promoted K.C.B. at the jubilee of Queen Victoria. Many other honors fell to his lot, among them honorary degrees of Oxford, Cambridge, Edinburgh, Dublin, and Munich Universities. His writings on pathology, surgery, and sanitary questions must be well known to you.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

JACOB'S LUNG INFUSION—PUERPERAL FEVER AND ANTI-STREPTOCOCCIC SERUM—NEW METHODS FOR SENSORY EXAMINATION—SCIENTIFIC CUROSITIES—HAND DISINFECTION.

BERLIN, July 9, 1904.

As the philosopher with forceful logic passes from proposition to proposition, in order to come to a necessarily evident conclusion for the reader, so must the scientific investigator add experiment to experiment in order, after the uninterrupted chain is finished, to have completed a structure of whose strength contemporaries will be convinced, and which will also be abundantly useful in the future. In such a way worked Jacob and his colleagues, and, on June 13, they placed the result of their work at the disposal of the world. Jacob said that the meagerness of the results of phthisio-therapy observed in institutional treatment, which indeed does not attack tuberculosis itself, is generally recognized, and directly attested by the large number of remedies tried. It is evident that these remedies even, if, as is the case with creosote, they kill the bacilli, cannot do their work, because they are too much diluted or do not succeed in reaching the place of their intended activity in the lungs. For years attempts have been made to treat the many who suffer from lung diseases directly by inhalations, yet, as is proved, the great mass of inhaled remedies reach only the upper air-passages, exactly as by intratracheal injection. On account of the danger of accident to neighboring structures, the attempts to inject medicaments directly through the chest wall into the lungs are not to be recommended. For these reasons experiments were made along a new line. First the animals were tracheotomized, a Nélaton catheter introduced through the wound, and 15-20 c.c of anilin-blue solution poured in. The animals showed no dyspnœa, no signs of suffocation, and the lungs on section were throughout colored blue. The animals in which, for control, methylene blue was injected subcutaneously and intravenously, at no time showed the color in the lungs. Of the larger animals, one goat that had been six times treated remained well and active. In order to utilize these proceedings for tuberculous patients, Jacob instituted experiments with Bougert, the veterinarian. First through a tracheotomy opening, by means of a catheter 40 cm. long, 50 c.c. of anilin-blue solution was poured directly into the principal bronchus of a non-tuberculous calf. Only a few slight coughs resulted from this interference. The calf bore equally well three infusions of 350-600 c.c. of anilin blue, at intervals of three days, and the lungs, when examined, were entirely blue. Then five tuberculous cows were procured, tracheotomized, and treated during five months, by means of a catheter one meter long, which had a funnel-shaped attachment holding 500 c.c. Sterile instruments and liquids were used. Five different agents were employed—creosote, old tuberculin, methylene blue, and pyoktannin, 1 per cent., and the injections were given in varying amounts up to one liter. Dyspnœa occurred only occasionally, and then was of short duration. For the most part, the animals went quietly back to the food in their stalls. A rise of 1° or 2° C. was noted in the case of each remedy, with tuberculin, 3°, but this lasted only thirty-six hours. Tuberculin proved of greatest value. The bacilli disappeared, the clinical symptoms became of lesser degree, and the weight increased. Bougert demonstrated the pathological findings in the case of the cows. The cavities were for the most part encapsulated, which otherwise seldom occurs. One could not expect a complete cure in cases already advanced. The value of this method for human beings was discussed by Professor Rosenberg. In his treatment, first the epiglottis and false vocal cords are painted with five-per-cent. cocaine, then sprayed through a tracheal sprayer with 1 c.c. of a two-per-cent. solution of cocaine and adrenal extract, which reaches the trachea and the beginning of the bronchi. Next, a small bougie, about 1 cm. in diameter, is introduced. When the epiglottis is passed, the mirror withdrawn, and an attempt made, keeping to the tracheal wall, to pass the catheter into the left or right bronchus. With a syringe, holding about 20 c.c., the liquid is then slowly introduced. The patient must breathe deeply, and lie down for the sake of the better distribution of the liquid in the lungs. The coughing, which now regularly occurs, does not force out the liquid, though it brings with it the danger of hemorrhage. However, in one hundred and fifty infusions, there has been no accident, and each procedure lasts hardly ten minutes. The dose for the injection is one-tenth of the usual subcutaneous dose.

In conclusion, Jacob discussed the results obtained so far in pulmonary tuberculosis. Five women who had been ill from one to six years, had numerous bacilli in the sputum, and were poorly nourished were treated during

three or four months with forty to fifty infusions. With all the patients the dose had to be frequently repeated for the sake of a strong reaction. The sputum completely lost its bacilli in from four to eight weeks, the physical condition improved greatly, and the weight increased from four to six pounds. From the point of view of diagnosis, the speaker said, lung infusion was a real advance. It made a diagnosis immediately possible in very light cases, and also, through a dose of tuberculin one-tenth as large, the differential diagnosis between tuberculosis of the lungs and that of other organs. If ½ to 5 mg. were injected subcutaneously, and no reaction followed, the patient was considered free from tuberculosis. If a reaction occurred, one-tenth as much of the solution used subcutaneously was injected into the lungs, and if there was still a reaction, pulmonary tuberculosis existed. If an increase in the dose was necessary, the tuberculosis was in another part of the body.

Our newly appointed professors, Bumm and Ziehen (not Fisher, as, through a misprint it was given in my letter of May 15), have already addressed the Medical Association. Bumm spoke, June 15, on "Serum Therapy in Puerperal Fever." Although, the speaker declared, the teachers of antisepsis have had signal success in surgery, this has not occurred with puerperal fever, especially in private practice. In the first six weeks of his Berlin service, the speaker saw six cases of puerperal fever. Two reasons make the treatment of obstetrical cases more unfavorable than that of other surgical cases. These are: (1) The long duration often in uncleanly surroundings, and (2) the neglect of antisepsis among midwives, which is not surprising, considering their multiform methods of action. Since therapeutic measures before employed, such as local antisepsis and general management, are no longer of avail, we must turn our attention to modern serum therapy. Animal experiments with serum having given many unquestionably good results, the speaker used it also with human beings. Bare statistical enumeration of the results is of no value, for the light cases are usually cured, and the severest cases still run their course to death. Therefore the speaker described his cases by groups. In five cases of septic peritonitis no result was observed. Of two cases of pure sepsis, one remained uninfluenced, while in the other a marked lowering of temperature was evident after each serum injection. Of two cases of sepsis with endocarditis, one became worse after serum injection. In four cases of pyæmia, no result was observed. In streptococcic endometritis, on the other hand, twenty-one out of thirty-two cases showed marked improvement after serum treatment, which was explained by a phagocytosis evident in the secretion. In conclusion, Bumm recommended in complicated labors the prophylactic administration of antistreptococcic serum. It was interesting that the Nestor of gynecology, Olshausen, followed Bumm's suggestions, and promised to institute experiments in his own clinic, in spite of the fact that his former experience had not been favorable.

On June 29 Professor Ziehen addressed the Medical Association on "Methods of Sensory Examination." While in the case of the eye and ear very exact methods of examination are employed, the methods of irritation which are used for testing the sensibility of the skin are never of like kind. The letters for ophthalmological examination have a definite size, and are read at a definite distance; in otology, definite sounds are used; only in examining the skin must one employ tests so uncertain as stroking with the finger, or the head or point of a pin. Such devices as the algesiometer and the æsthesiometer are unsatisfactory. For years the speaker had worked to improve this technique. His first attempts made use of falling balls, which, however, fell from that part of the skin struck, to the ground, and so were impracticable. A swinging pendulum was more practicable, which, in proportion to the height from which it fell, made an exact and ascertainable tactile irritation. But even with this, inexact results were obtained, for the pain points of the skin, which are points especially sensitive to pain were, through contact with the needle, very sharply excited. For this reason, the needle point was replaced by a sharp edge. First by this instrument was it established that the range of perceived impressions in the skin is surpassed by that of the ear or eye. Using the unit of strength of physics, the eye recognizes 1-1,000,000 erg, the skin only the hundredth part, 1-10,000 erg. Indeed, the skin is so little sensitive that this apparatus could not be used to determine increase in excitation. For this a light pendulum was used, which consisted of a thread with a metal pearl on the end, and just above this a little ball made of elder With these two implements a number of interesting results were obtained. It had but recently been recognized that the dulling of perception in tabes, for instance, was only an exaggeration of the physiological condition. For one normally feels first touch and then pain, and in tabes it is only that the time between the recognition of touch and pain is increased.

In the same meeting von Bergmann presented a German soldier, who had been wounded in Africa, as an example of the power of resistance of the human organism. The man was attacked by a mob of natives, wounded on the head, right shoulder, and elbow, and shot in the breast. With great difficulty, and robbed of all his clothes, he dragged himself along for a distance of nearly twenty-five miles. A Hottentot girl helped him, and so he succeeded in reaching a physician, who found a hæmothorax. In spite of the already developed sepsis, the large wound healed, the bullet becoming encysted.

Simmhuber presented a case of anatomical irritation phenomenon of the pharynx and larynx, which, added to the two cases of Oppenheim and Spencer, makes the third on record. It occurred in a man who, in 1899, had double vision; and in 1901 right-sided apoplexy, with increase since August, 1903. Since then he had had headache, dizziness, staggering gait, and difficulty in speech. A constant rhythmical twitching of the soft palate, pharynx, and larynx, had been observed. The false vocal cords made forty vibrations to the minute. The lesion was to be looked for in the posterior cranial fossa.

In the Obstetrical and Gynecological Society, Nagel demonstrated a parovarian cyst, with a capactiy of 33 liters, the largest before reported having a capacity of only 23 liters.

In the same society Schäffer brought up again the old, but ever new, question of disinfection of the hands. There are three reasons which explain why the results of the various workers in this field are so different: Namely, the different methods of investigation, difference in the condition of the hands on different days, and, finally, variations in the vigor of manipulation. Therefore only those experiments in which special objects, as glass pearls and silk threads, have been used should be considered scientific. For ten years the speaker had carried on experimental investigations, and had arrived at the almost universally accepted opinion that we possess no antiseptic which, in a practical degree of concentration, can kill pus-forming bacteria on the hands in from five to ten minutes. The demonstrated cultures, with one exception, were not sterile. This one was from disinfection by alcohol, which the speaker used exclusively. In the discussion, Strassmann expressed his doubt of the efficacy of alcohol disinfection and his fear of the injurious effects of the alcohol on the skin. He used rubber gloves extensively. Kohlank stood for thorough mechanical cleansing; Blummberg, for bichloride of mercury; Olshausen, for the old Fürbringer method, with thorough mechanical cleansing. Hartmann and Bumm were of Olshausen's opinion. The last mentioned strongly favored rubber gloves.

ADENOIDS IN CHILDREN.

To the Editor of the Medical Record:

Sir: In the issue of the Medical Record for August 6, 1904, appears an abstract of a paper by Dr. Clarence C. Rice, entitled "The Conditions Which Interfere with Complete Success in the Operation for the Removal of Adenoids," which was read by him at a meeting of the Medical Society of the County of New York, on May 23, 1904, in which the statement is made that adenoids are always present in children with nasal catarrh.

In this opinion I believe the majority of nose and throat specialists will not concur, for I am confident that nearly all of them can point to experiences similar to those I frequently have had in which children thus afflicted did not concurrently present adenoids. In a paper published in the *New York Medical Journal* for June 30, 1900, bearing the title of "The Rôle of Purulent Rhinitis of Childhood in the Production of Atrophic Rhinitis," I reported two cases of long-standing purulent rhinitis in which there was absolutely no trace of adenoids. At the time I stated that "I should regard these cases as decidedly contradictory to the statement of Herbert Tilley and others that purulent rhinitis of childhood is due to adenoids." Since that time I have seen other cases with similar symptoms in which adenoids were absent. I believe that adenoids are present in most children who are brought to us for advice concerning nasal disorders, but I am not yet willing to subscribe to the opinion held by some that nature has not been more considerate of these of her creatures than to afflict nine out of ten children with adenoids. As to the conditions which interfere with complete success in the operation for the removal of adenoids, I think Dr. Rice should place his second conclusion first, viz., that the lymphoid tissue was not thoroughly removed; but next in order as to the cause of failure I would suggest that failure to secure performance of the operation when the child is young, that is to say, before the seventh or eighth year, be considered.

Richmond McKinney, M.D.

Memphis, Tenn.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 11, 1904.

Subperiosteal Fractures of the Humerus in Children.—J. S. Stone describes five cases illustrating the risk of overlooking subperiosteal fractures in children. Crepitus and abnormal mobility were absent, deformity was slight, pain and tenderness were not marked, passive motions were possible in all directions, but the deltoid could not be used. It occurs in children too old to have green-stick fracture. In subperiosteal fractures the radiograph shows slight lateral displacement with a transverse fracture. The toughness and strength of the periosteum prevent displacement and crepitus. After a fall on the hand, arm, or shoulder, inability to abduct the arm, with absence of the ordinary symptoms of fracture, should lead to careful search for localized tenderness anteriorly just below the head of the humerus and slight irregularity in contour at that point. The presence of these signs should establish the diagnosis of subperiosteal fracture.

The Physical Relationship of Finsen Light, Röntgen Ray, and Radioactivity.—Wallace C. Sabine tells us that in looking for that which all three of these forces have in common, we shall find it in their ionizing effect—the breaking of molecules into subatomic particles, charging the larger with positive and the smaller with negative electricity. This effect common to the three is perhaps the intermediate process preliminary to the final physiological result. Ultraviolet light differs from visible light only in the frequency of its vibrations, while visible light differs only in frequency from electro-magnetic waves. In wireless telegraphy the electric spark produces vertical electric waves and horizontal magnetic waves. Röntgen rays are in many respects similar to light rays. They are produced by a negatively charged particle abruptly stopped by striking against the platinum disk in the center of the exhausted bulb. The result is a very thin wave or pulse sent off into the ether. This thinness is the source of its great penetrating power. The radiations from radio-active bodies consist of the emission of positively charged particles, negatively charged particles and an ether pulse. The Röntgen rays and the gamma rays, or ether pulse, differ only in thickness. An atom is now known to be a composite body capable of being split up. When a part is torn from the atom the two parts so torn apart are called ions. This splitting up may be done in various ways; ionization may be produced by almost any violence, by electricity, by the passage of the Röntgen rays, by the radiations of radio-active substances. All three of these physical processes are electrical, the ultraviolet rays as well as the others. Their first effect is that of electrical violence upon the atom, which results in an increased atomic energy and a resulting ionization.

Causes and Treatment of Malpositions of the Uterus.—D. J. Brown classifies retrodeviations as follows: A, Virginal: (1) congenital; (2) puerile, in which a full bladder combined with a congenital shortness of the anterior wall are the factors; (3) senile atrophy; (4) overdistention of the bladder; (5) habitual constipation; (6) masturbation; (7) constitutional disease, as anæmia and chlorosis. B, Parous women: (1) puerperal metritis or subinvolution; (2) laceration or over-stretching of the pelvic fascia; (3) salpingitis; (4) pregnancy; (5) pressure of clothing; (6) traumatism; (7) neoplasms; (8) impotence in the husband; (9) wandering spleen. Anteflexion accompanies non-development of the uterus due to over-exercise or sewing-machine running, and shortening of the uterosacral ligaments. Immobile retroposition with anteflexion may follow labor and abortion with posterior adhesions. Excessive mobility of the uterus results from laxity of the ligamentous supports. The non-surgical treatment of the conditions considered must depend on the symptoms, length of displacement, and complications that exist. The uterus should first be replaced and retained by pessary or tampons. General tonics should be used, and hot vaginal douches, with the use of the knee chest position daily. When the uterosacral ligaments no longer retract the author recommends Goelet's operation for fixing the posterior surface of the cervix to the posterior surface of Douglas's cul-de-sac. The author is not enthusiastic over Alexander's operation. For anteflexion due to muscular relaxation he recommends electricity, stimulating hot douches and tonics. If operation is necessary he uses Dudley's operation. If there are adhesions, incise the posterior fornix, break up adhesions, and pack the cul-de-sac. Complete prolapse results from backward displacement with relaxed uterosacral ligaments, combined with a subinvoluted uterus and a relaxed vaginal outlet. The author believes ventrofixation and round ligament fixation to be unscientific. Rest in bed must be insisted upon; then the cervix may be repaired or made smaller and anterior or posterior colporrhaphy done.

Journal of the American Medical Association, Aug. 13, 1904.

A Case of Brass Molders' Ague.—Stephen R. Pietrowicz reports the case of a Pole, thirty-three years old, a brass molder, who came to this country fourteen years ago and began working at his occupation, in which he continually inhaled an atmosphere laden with minute particles of brass filings. One year later his symptoms began. He first noticed palpitation of the heart, accompanied by pain in the precordial region; also a dull pain in the abdomen, sometimes lasting for hours. Numbness and cramps in arms and legs were not infrequent phenomena. A prominent symptom was a fine tremor, well marked in the muscles of the face, hands, and fingers. Distinct chills were frequent. Constipation was obstinate. Appetite became impaired. He had severe bronchitic symptoms. He was confined to his bed, sometimes for weeks at a time. Recently severe headache, attacks of vertigo, dizziness, and a burning sensation in the epigastrium have been noted. His hair is falling out and his memory is failing. Examination shows a tongue heavily coated, with foul breath, and a beautiful green zone or border along the gingival margin of the gums, which cannot be removed by ordinary scraping. Patellar reflexes are exaggerated; ankle-clonus is present. Arteriosclerosis is marked. Iodide of potassium was given until physiological reaction appeared. Milk, given very hot but not boiled, afforded a great deal of relief. It was given with the idea that it would precipitate both zinc and copper into insoluble albuminates. No marked improvement followed the use of bromides and iodides. Large doses of tonics were given. On his entering the hospital it was found that anything hot was soothing to him and relieved his pain. Hot water was then tried to which was added gum camphor, 5 grains to a pint of hot water; he would drink at times two to three pints of this with great relief. Large mustard plaster over the entire abdomen gave him great relief. Total abstinence from all meat was followed by improvement, and he has since been put upon a strictly vegetable diet, with no return of symptoms.

The Medical News, August 13, 1904.

Difficult Cases of Infant Feeding.—Theron Wendell Kilmer regards improper feeding, and especially feeding with too large percentage of proteids, as the usual cause of difficult digestion in infants. Feeble digestion may begin at birth; it may be the result of acute disease. A baby may be a chronic vomiter because he is jounced or handled after feeding. The author begins treatment in a case of difficult digestion by stopping the food given, washing out the stomach daily, and flushing the colon and rectum. He gives only barley gruel for several days; then adds a teaspoonful of cow's milk to one feeding, and watches for curds. If none appear, he gradually increases the amount of milk. The baby is to be weighed naked every day. One should never feed a sick baby on special formulas, he says; they are only for healthy children. In some cases it will be necessary, when the baby vomits continually, or refuses food, to feed it with a stomach tube. It may retain the milk in this way. Condensed milk is not suitable for constant use, but may be of great value on a journey, or to tide over a hot spell when fresh milk cannot be kept.

Hereditary Syphilis.—Howard S. Kinne says that when syphilis is inherited it is the eldest child that suffers most, and often he alone. Hereditary syphilis is constitutional from the first; for the first two years the secondary and tertiary manifestations appear together, later they are tertiary alone, and about puberty they are apt to be marked. Hereditary syphilis impresses on the general nutrition a profound alteration. Hutchinson says it is difficult to diagnose hereditary syphilis; we must have combined snuffles, ham-colored eruptions, especially about the anus, general wasting, senile physiognomy, etc. The child may be healthy at birth and show no symptoms for six weeks. He then has ham-colored eruption and snuffles, hoarseness, anæmia, and wasting, with the look of an old man and a wrinkled skin. If the disease be not severe and treatment is successful the symptoms will be put off until puberty. The administration of mercurials to a syphilitic mother during pregnancy will reduce the liability of the offspring to be affected. Nutrition must be of the best. Mercury must be administered at once and later potassium iodide.

Report of a Case of Ruptured Ectopic Gestation.—John W. Coe reports a case of ectopic gestation which presented considerable difficulty in diagnosis. During her eight years of married life, the patient had had two previous attacks of abdominal pain, which had been diagnosed as renal colic. The last regular period occurred only thirteen days before the patient's first attack of abdominal pain, accompanied by a chill. One week later she had a sudden abdominal pain accompanied by nausea, vomiting, and

weakness. No tenderness or rise of temperature or pulse remained three hours after this pain. The urine was highly acid, of high specific gravity, and contained red blood-cells. It had not been drawn by catheter, but there was no vaginal hemorrhage. Two days later she again had pain, with rise of temperature and marked prostration and fainting. The red blood-cells were reduced nearly one-half, and there was a leucocytosis of 22,000. For two weeks there was irregular rise of temperature, with steadily improving general condition. A good-sized mass could now be felt on the right side of the abdomen. The diagnosis of extrauterine pregnancy was confirmed by the result of operation. The mass contained placental tissue and clusters of decidual cells.

New York Medical Journal, August 13, 1904.

Is Milk a Factor in the Spread of Tuberculosis?—J. O. Cobb has collected some statistics to show that tuberculosis is as prevalent in countries where cow's milk is not used as it is in those where it is a prominent article of food. In the Island of Guernsey the cattle are free from tuberculosis, yet the human inhabitants are afflicted with the disease. In Iceland it is prevalent, yet the cattle are said to be non-tubercnlous. In Alaska milk is not used, yet the Indians are affected by tuberculosis. The same is found to be the case with the Chinese, the Japanese, the Hindu whose religion prohibits the use of meat and milk, and in the Philippines. In none of these countries are cattle kept for the use of meat or milk for food. The author inclines to the opinion that it is a disease of filth and poverty. Tuberculosis among cattle as well as among the human race is a disease of contact. The ultimate source of this contagion is as yet unsettled.

Symptomatology of Morphinism.—Charles J. Douglas recalls some of the less known symptoms of morphinism. The first objective symptom is often languor and general debility in the morning. The patient is ill in the morning, well and even brilliant by night. He does his best work at night. At the same time he has a desire for food at night, and especially for sweet foods, candy, pie, cake, etc. Cigarettes are also grateful in plenty. Perfumes are desired. They are abnormally sensitive to cold, and do not love to bathe. They have poor memory and often misplace things. Procrastination is a common characteristic. The ethical side of the brain seems paralyzed and truthfulness is impossible. The moral symptoms are secondary to the physical suffering. The deleterious effects of morphine are dependent more on the length of time it is used than on the amount taken. Half a grain daily for ten years will produce more serious consequences than ten drains daily for one year.

Aberrant Thyroid Tissue, and Its Relation to Intratracheal Growths.—Jeremiah S. Ferguson reports a case of aberrant thyroid. Such aberrant masses of thryroid tissue occur more frequently above than below the thyroid bone. They are much more frequent than is ordinarily supposed. Gruber found twenty-three cases in three hundred autopsies. The author's case showed the mass lay on the right side of the trachea, extending around beyond its middle. There were several isolated fusiform masses in the posterior wall, close to the ends of the cartilaginous rings. A strong band of muscular tissue surrounded the thyroid mass, and many fibers ended among its cells. It had an irregular, apparently advancing border line; small border cell groups were separated by dense fibrous membranes, isolating them from the neighboring thyroid masses. These outlying groups were composed of small and less developed follicles, containing colloid material. These groups appeared to be pushing toward the inside of the trachea, but to be stopped by the dense fibrous membrane between the cartilaginous rings. The author thinks that the case is suggestive of an early stage of development of an intratracheal tumor, a stage in which none of the thyroid tissue had yet broken through the tracheal wall.

American Medicine, August 13, 1904.

A Plea for the More General Use of Ether, with Description of the Drop Method of Administration.—B. F. Stevens claims that ether can be taken just as easily and with much less danger than chloroform. It took an average of eleven minutes to produce surgical narcosis in the one hundred cases of which he kept notes; in forty chloroform anæsthesias it required an average of six minutes to induce narcosis. The disagreeable odor of the ether can be avoided by using ten or twenty drops of oil of gaultheria on the mask for three minutes before beginning with the ether. Ether is contraindicated, of course, in asthma, advanced pulmonary tuberculosis, chronic bronchitis, and marked arteriosclerosis. It should be borne in mind that when the heart ceases to beat when chloroform is being given, it is almost impossible to start it again, while in ether narcosis, the heart continues to beat a long time after respiration has ceased. A Laplace inhaler is used, which is easily cleaned With this mask he uses the drop method. The eyes should be protected by a large moist cotton compress. Before the patient is removed from the table he advised the giving of an anema of normal saline solution, which allays the thirst and is of value when much blood is lost. If the patient has been asleep twenty-five minutes or longer, he washes out the stomach with a warm solution of sodium bicarbonate, followed by warm normal salt solution.

Case of Acute Suppurative Pancreatitis.—Miles P. Porter reports the following case: Mrs. W., aged twenty-two, had one child and one miscarriage. Five years ago she had typhoid fever and had been having boils for four or five weeks prior to present illness. Family history is good. She was taken suddenly ill with pain in the abdomen and vomiting; eight hours later she had a temperature of 104 F. and pulse 110. She was menstruating when taken ill, but this stopped in twelve hours and did not return. Twelve hours later she went into collapse. The next day, twenty-two hours after onset of disease, the pulse was 160 and temperature 105.8° F. The abdomen was tender and distended. Black and grumous passages were examined microscopically and showed very few red cells. Her lips were not pale. At consultation it was decided that a positive diagnosis was not possible, but the probabilities were in favor of a ruptured tubal gestation. No operation was performed and death occurred sixty-six hours after onset of illness. Postmortem was done eleven hours after death, and the abdomen was found to be bathed in pus. The head of the panereas was about one-half destroyed. The uterus and appendages, the spleen, the liver and hollow viscera, were normal. It was highly probable that the infection was carried to the panereas by the blood stream from one of the boils.

Illustrative Cases of Myelogenous Leukæmia.—George H. Evans presents the histories of three cases of myelogenous leukæmia, and calls attention to the results of the *x*-ray treatment which has been and is being carried out in two of them. In one case the patient was symptomatically cured and, in the other, while there has been improvement, there has not been any marked improvement in the red cell count. Our conception of the pathology of leukæmia is for the present hopelessly tangled up. As the result of investigations of Pappenheim, Walz and Grawitz, Michaelis, Wolff, Taylor, and others the following theories may be presented: (1) The large mononuclear leucocyte is the mother cell, ordinarily capable of further differentiation into either the ordinary bosophilic cell, or into a neutrophilic myelocyte. (2) The two forms of leukæmia, lymphatic and myelogenous, are closely associated, and probably are forms or stages of the same disease. (3) Lymphocytes are formed in the lymphoid tissue of the bone marrow, and not exclusively in the lymph glands, as formerly supposed. (4) Myelocytes are formed in the bone marrow, and are the parent cells of the polymorphonuclear neutrophiles. (5) In myelogenous leukæmia, myelocytes are cast into the blood circulation, in all probability because of increased activity of the myeloid tissue of the marrow, which is the only tissue primarily affected in this disease. It would seem that the Röntgen rays, penetrating the structure of the spleen or other tissue, was capable of producing tissue changes, which alter, temporarily at least, the symptom-complex of this disease. Further investigation of this method of treatment by scientific men is demanded.

The Lancet, August 6, 1904.

The Relation of Inebriety to Insanity and Its Treatment.—Robert Jones speaks of the forms of mental disorder resulting from alcohol as gross dementia, maniacal, unrestrained excitement due to hallucinations, or permanent delusional states. The susceptibility of the brain and nervous system through inherited or other vice determines whether a given case shall be considered a lunatic, an inebriate, or a chronic drunkard. Of all the special symptoms characteristic of forms of alcoholic insanity the condition termed "paramnesia" is the most indicative. This is the failure of memory for recent dates, an impairment of nerve cells by which the brain is able to retain the images of past sensations and in consequence of which there is a marked loss of the power of associating ideas. All drinkers become subject to sensorimotor disturbances and tremors. After considering the sensory symptoms, susceptibility and general results of alcohol Dr. Jones says that the treatment of inebriety resolves itself into the general treatment of drunkenness and that of the individual, and this has become a question for the statesman, the reformer, and the philanthropists.

Serum Therapy of Anthrax.—Ivo Bandi gives a detailed account of two cases of general anthrax infection successfully treated by him with anti-anthrax serum. Examination of these cases clearly proves that, although isolated, they give stronger support to treatment with anti-anthrax serum than is to be drawn from a long series of cases of simple external anthrax successfully treated with anti-

anthrax serum at the outset under conditions which leave it doubtful whether the usual local treatment destructive of the original seat of infection might not have been of itself sufficient to arrest the progress of the disease. In both the cases described the clinical and bacteriological examination confirmed the diagnosis of exceptionally severe general anthrax. In both cases, but especially in the first, the serum was used when the signs of serious general poisoning were chiefly apparent in the œdema which had spread far from the primitive seat of infection, in grave disturbances of the circulation, and in the evident lesions of the kidneys. Moreover, in the first and most serious of the two cases the action of the serum was rapidly decisive when free cauterization of the primitive seat of infection had completely failed. The double action of the anti-anthrax serum—antibacterial and antitoxic—is plainly evident, its antibacterial power being shown by the immediate arrest of the progressive invasion of the organism by the bacillus, and its antitoxic power by the sudden improvement in the general condition of the patients and by the complete *restitutio ad integrum* of the renal function immediately after the use of the serum. The author would insist on the necessity of treating such severe cases energetically by injecting into the veins large doses of the specific serum. For while, on the one hand, no justifiable opposition can be made to the treatment when carried out with proper caution, in the practical result its antitoxic action is so immediate as to suggest rather a rapid neutralization of the toxins circulating in the system than a stimulating action of the specific principles contained in the serum on the natural defensive powers of the organism.

Some Points in the Diagnosis and Treatment of Heart Lesions.—John Hill Abram treats of eighty-one cases of heart disease that have come under his observation and, in a rapid résumé, the preponderance of mitral cases, nearly half the number, and the importance of rheumatism in their causation stand out prominently. Cases bearing upon points he wishes to emphasize are recorded. The treatment is outlined under the three following headings: (1) Compensation practically equal to the lesion. Excesses, mental as well as physical, should be warned against. Moderation in the use of alcohol and tobacco should be enjoined. General hygienic and dietetic measures should be considered. Even in this stage in mitral stenosis there is a risk of hæmoptysis or embolism. If hæmoptysis occurs, give a free purge and a dose of opium. If a female, aortic trouble is a bar to marriage. Well-compensated mitral regurgitation cases often pass through pregnancy without trouble; in stenosis cases grave symptoms arise and notably attacks of tachycardia or acute œdema of the lungs. In cases of mitral stenosis marriage should be advised against. (2) Compensation only equal to the lesion when the patient is at rest. In aortic cases, with throbbing in the neck vessels, headache and giddiness, the best treatment is a week in bed with limitation of fluid and regulation of diet and moderate purgation. Bromide and iron often give relief. General tonics and small doses of tincture of digitalis will help to place the case in subdivision No. 1. (3) Compensation unequal to the lesion. Limitation of fluids is often of great service. The bowels may be gently acted upon. In aortic cases excitement and even maniacal attacks may be present, and here trional or sulphonal and paraldehyde sometimes suffice, but opium is the sheet anchor. When engorgement of the liver and stomach had been marked good service had been rendered by the pill containing squill, digitalis, and mercury. In aortic cases with thickened arteries and increase in tension of the radial pulse, the best line of treatment is to limit the intake of fluids, open the bowels, and give renal diuretics. If cardiac stimulants are indicated he prefers strophanthus. Even in cases in which the pulse tension is low, digitalis is demanded, and he does not hesitate to give it in an aortic case when the mitral valve has yielded.

Deutsche medizinische Wochenschrift, July 28, 1904.

Treatment of Alopecia Areata by Direct Radiation.—Kromeyer compares the rays derived from the carbon electrodes as used by Finsen and those of iron, which were discarded soon after their introduction because it was believed that they had little penetrating power. He believes that the latter are the most practical however, as they can be used close to the skin without the intervention of the "pressure lens" in the Finsen apparatus. Six cases of advanced alopecia were treated by this method, which had resisted all the other known devices. The rays were applied for a period of about two weeks until a marked reaction was secured, followed by an interval during which the effects were observed. Then the treatment was repeated. All the patients developed a growth of hair which was permanent, in some instances the new growth was observed within eight days after the first treatment. Kromeyer does not believe that alopecia is a parasitic disease. The success of this treatment depends on the fact that the superficial irritation produced by the rays extends along the hair follicles and stimulates the root of the hair to a new growth.

The Immunization Treatment of Tuberculosis.—Carl Spengler proposes the use of tuberculin derived from cattle (perlsuchttuberkulin) for this purpose. This he prepared in a similar manner to that made from the human bacilli, and the dosage is similar to that of the old tuberculin. The injections are made in the forearm and the next one not made until the inflammatory reaction from the previous one has subsided. The general condition of the patient must largely determine the rapidity with which the injections are made. Where the latter are contraindicated or can only be done at prolonged intervals, the effects of the treatment can be hastened by tuberculin inunctions, which are especially applicable in children. As the result of clinical experience, the author found that the effects of this procedure in tuberculous patients were similar to those observed with very much weakened tuberculins derived from the human bacilli. The temperature reaction is comparatively slight and the subjective symptoms correspondingly diminished. The local reaction is more marked, however, than with the other tuberculins, and this is also accompanied by a more marked reaction in the tuberculous lesions. There seemed to be no toxæmia following the use of the preparation, as is often seen with the other varieties of tuberculin.

Clinical Experience with Renal Decapsulation in Bright's Disease.—P. Rosenstein reports the results of Edebohls' method of treating chronic nephritis in six cases, with an unsatisfactory outcome. One patient died as the result of the operation, one became worse, two were uninfluenced, and the remaining two were in some respects improved Rosenstein claims that the favorable results reported by Edebohls were influenced by the fact that his cases were not true instances of Bright's disease, but were simply inflammatory processes brought about by the abnormal mobility of the kidney. Moreover, among the cases reported by Edebohls were nine which were designated as presenting a unilateral Bright's, which Rosenstein insists does not exist, as the process, being due to toxins held in solution, is always bilateral. Rosenstein concludes that the renal decapsulation in severe Bright's disease is a very dangerous procedure, being attended by a mortality of 26 per cent. Permanent cure has not been attained in a single case of undoubted Bright's disease. The only improvement in Rosenstein's cases are as follows:—objectively, in one case the disappearance of a slight œdema, but no improvement in albuminuria; subjectively, in another case the disappearance of headache and visual symptoms which were present before the operation.

Berliner klinische Wochenschrift, August 1, 1904.

Lowering of the Freezing Point of the Blood in Cancer Patients.—K. Engel discusses the claims made by Israel and Engelmann that the freezing point of the blood in this disease was lowered, and which they ascribe to the fact that the blood becomes impregnated with toxic substances of an albuminoid nature. In order to arrive at a definite conclusion, the author instituted a special investigation in thirteen cases of carcinomata in various parts of the body. He found that in no case was there abnormal lowering of the freezing point. In a few there was a value of - 53 or -54. The question as to whether the concentration of the blood can be increased by the carcinoma itself, independent of its localization, cannot yet be definitely decided from the data at hand.

Atheroma of the Aorta in Rabbits after Injection of Adrenal Extract.—C. v. Rzentkowski injected three or four drops of a 1:1000 solution of adrenal extract into the ear vein of a rabit every two days. In three out of four cases it was found that the animals on autopsy presented cardiac hypertrophy, circumscribed calcification areas in the media of the aorta with a tendency to the formation of aneurysms, hepatic cirrhosis, and hyperæmia of the kidneys (two cases). Calsification was observed in one instance after the injection of only nine drops. The author is not prepared to state whether the process is really an atheroma. He considers that it is a primary calcification, accompanied by a small-celled infiltration of the surrounding diseased tissues, rather than a secondary calcification. It was found, moreover, that this process caused a marked diminution in the elasticity of the vessels, due to a peculiar degeneration of the elastic fibers. Probably an increase of blood pressure which extends throughout the entire circulatory system, is at the basis of these changes. It is impossible to say, however, why the calcification process should be thus localized.

Munchener medizinische Wochenschrift, July 26, 1904.

Influence of Anomalies of the Bony Thorax.—Bäumler discusses the effects of these conditions on the pulmonary percussion note and on the position of the heart, and calls

attention to the fact that unless they are carefully noted, mistakes may readily result. The form of the thorax and the position and curvature of the individual ribs have a marked effect on the percussion note of any given area of the lungs. The costal relations are dependent to a large extent on the condition of the vertebral column, and any slight variations in the latter markedly affect the form as well as the position of the ribs. When differences in the percussion note on both sides of the chest are detected it is essential that the symmetry of the two halves of the thorax should be carefully studied, particular attention being paid to the supraclavicular and supraspinal regions. It will be readily seen that this might modify the findings in a suspected case of pulmonary tuberculosis. Estimates as to the size and position of the heart are also influenced by anomalies of the chest. Thus, variations in the intercostal spaces due to changes in the curvature of the thoracic segment of the column will bring about apparent changes in the size and the apex beat of a perfectly normal heart.

The Hygiene of Smoking.—J. Bamberger believes that in considering the dangers attendant upon the habit of using tobacco, two classes of smokers must be differentiated. One includes those who smoke cigars with the aid of a mouth-piece or, if not, are careful not to keep the end of the cigar saturated with saliva. This class also includes the pipe smokers. The other contingent comprises those who chew the end of the cigar or keep it wet constantly. The first class is much less apt to be affected by the absorption of the various products of the dry distillation of tobacco than the second. In the former, however, the smoke may give off its toxic constituents in the moist buccal cavity, whence they are swallowed with the saliva, or the smoke is drawn in with the inspired air and so diffused over the lungs. The second class in addition also swallow the nicotine which has been dissolved out of the tobacco by the saliva. They are therefore exposed to greater danger, and if indulgence in alcohol is also added, the condition is aggravated. The "dry smokers" are found to suffer much less from disturbances due to the use of tobacco than the "wet smokers," and he would recommend that this precaution should always be insisted upon. The suggestion that a bit of cotton saturated with a solution of iron chloride be placed in the mouth-piece of a cigar holder, he fully recommends and claims that a certain quantity of harmful products are thus rendered innocuous.

Severe Nephritis Following Inunctions with Balsam of Peru.—A. Gassmann believes that the use of balsam of Peru in scabies is a procedure fraught with considerable risk, especially as it is very apt to be employed in persons with a delicate skin, women and small children, because it apparently is accompanied by no irritation of the skin. A number of instances have been reported in which the use of the balsam caused renal irritation, but the case instanced by the author is remarkable for the severity of the symptoms. The patient, a young adult of twenty-six, was perfectly healthy previous to the inunction on two successive evenings of about 25 gms. of Peru balsam mixed with vaselin. Five days later he presented the symptoms of a severe nephritis which was almost fatal. It was not possible to say whether any previous kidney lesion had existed, but if so, this was undoubtedly an acute exacerbation. The preparation was practically pure. There was probably an idiosyncrasy present in this case, but it would be well to determine this in every patient for whom large quantities of the drug are to be employed.

French and Italian Journals.

Cancer of the Body of the Uterus.—A patient who was suffering from cancer of the body of the uterus came under the care of M. H. Géraud. Géraud performed abdominal hysterectomy. The patient was a woman fifty-six years of age who had previously had a fibroma which had been cured during the menopause. A period of two years without discharge from the uterus separated the disappearance of the fibroma from the appearance of the cancer. Ten months and a half have elapsed since the hysterectomy was performed, and as yet there has been no recurrence.—*La Presse Médicale*, July 16, 1904.

Cerebral Abscess and Fetid Bronchitis.—M. Porot describes the post-mortem appearances in this case. The abscess was very limited in extent, and was situated in the right lateral ventricle, in the posterior part. The enveloping membrane was thick, and its structure showed that it had existed for some time. At the base of the abscess there was a small channel extending forward. This abscess co-existed with a right-sided bronchiectasis, which was extremely fetid. The odor of the cerebral pus resembled that of the lung. The patient entered the hospital with right hemiplegia, which had developed after a series of epileptiform crises. Sharp pain was felt on pressure of the extremities. The temperature was elevated. Expectoration was abundant and fetid. There were signs of bronchitis. The patient had been an epileptic since the age of five years. He died eight days after his entrance to the hospital.—*Lyon Médical*, July 17, 1904.

Treatment of Aneurysms by Subcutaneous Injections of Gelatinized Serum.—Gley is interested in the coagulating action of gelatin. He has made certain experiments in the past, which give grounds for stating that the coagulating property of gelatin is due to the very small quantity of calcium chloride contained in it. It is precisely this fact—the very small quantity of calcium chloride, that imparts to the gelatin its coagulating power. If this quantity were larger, the power of coagulation would not exist. Gley proposes to conduct further experiments in this subject. In the first place, he is going to study the effect of injections of sodium chloride, and later the effect of injections of decalcified gelatin. The results of these experiments will show the part played by gelatin, and also by calcium chloride in blood coagulation.—*Le Bulletin Médical*, July 13, 1904.

Diphtheritic Angina Developing in a Child in Spite of an Injection of Antidiphtheritic Serum.—E. Weill and M. Péhu report a case of this kind and emphasize the necessity of taking other prophylactic measures, such as isolation and disinfection. In the service of the writers, a child developed diphtheria on May 16. All of the other little patients, both those already in the hospital and those entering later, received an injection of antidiphtheritic serum. One child who entered the hospital on May 18, although receiving the injection, developed a membranous angina on June 5. Diphtheria bacilli were cultivated in pure culture from this membrane. It was discovered later that the first child had escaped from its isolated quarters to play with the second child. This was the only case of infection out of thirty-three. The writers state that even in strong doses the injections are not dangerous. The employment of this preventive measure should be general.—*Lyon Médical*, July 17, 1904.

Tuberculous Ostitis with Cold Abscess of the Lower Angle of the Shoulder Blade.—M. P. Bourgine describes this unusual case. The patient was a woman of fifty years. The family history was bad, the father and mother both dying of pulmonary tuberculosis. The patient had already been operated on for cold abscess of the cervical region. For six months she had suffered with pains at the lower extremity of the left shoulder blade. She had lost flesh and had no appetite. Auscultation revealed signs of pulmonary tuberculosis at the apices of the lungs. The tumor at the shoulder blade was as large as a mandarin. Fluctuation was not clear. Diagnosis lay between a lipoma and a cold abscess. Operation revealed a pocket of tuberculous pus. The lower part of the shoulder blade was the seat of ostitis, and at one point the bone was necrosed and perforated. The patient recovered comfortably from the operation.—*Journal des Sciences Médicales de Lille*, July 16, 1904.

Clinical Contribution to the Therapy of Trichiasis.—Francesco Baroggi reports the results of the operative procedures used for the cure of trichiasis in the clinic of the University of Pavia. During the last fifteen years there have been eighty cases of this disease operated on by the method of Jaeske-Arlt, with successful results in all but two cases. The ages were from seventeen to fifty-five years. The best results are obtained in adults, and especially in advanced age, when the cases present the greatest obstacles to the surgeon. The disease results from a chronic trouble of long standing, and has occasioned much suffering and injury to the cornea before the patient will submit to any operation. Nevertheless, by the Jaeske-Arlt operation the best results can be secured. Several cases had been operated on unsuccessfully by other methods, and ten had to be operated on twice, owing to the continuation of the original disease producing a recurrence.—*Gazzetta Medica Lombarda*, June 20, 1904.

Mucoid Ovarian Cysts.—Mauclaire states that these cysts generally involve only one ovary. They grow to enormous size. Recurrence is rarely observed after oblation. As the cyst develops it ascends into the abdominal cavity and becomes pediculated. From this fact possible complications may occur. Torsion or rupture of the pedicle is accompanied by intracystic hemorrhage. This torsion is especially frequent during pregnancy. The uterus may be displaced by a cyst, ascites may develop, or adhesions to the intestine may form. The contents of the cyst may suppurate. The cyst may rupture. The prognosis of the mucoid cyst is generally good. The growth should be removed at an early stage and pregnancy is not a contraindication to this operation. If both ovaries are involved total hysterectomy should be performed. When the stage of cachexia has been reached operation is contraindicated.—*Journal des Praticiens*, June 18, 1904.

Diplococci Polyarthritis.—Alfredo Baduel reports a case of polyarthritis following acute pulmonary trouble, in

which Fraenkel diplococcus was found in the secretions of the diseased joints and pleura. Since 1883, cases have been recorded in which pneumonia has been followed by involvement of the joints lasting some time. The diplococcus of Fraenkel has been demonstrated in these joints, and has been regarded as the etiological factor in the affection, the disease resulting from the toxins formed by the diplococci. The author's case was that of a man of thirty-seven years. He was attacked by bronchitis, which in about ten days developed into an acute pulmonary process with high fever, pain in the chest, and cough. A purulent effusion developed in the chest, and after some time the joints began to swell. All the joints became involved; they were painful and tender on pressure, but not reddened. The involvement of the joints was accompanied by fever, from 38° to 39°. The course was chronic, lasting some three months. The diplococcus of Fraenkel was demonstrated in the pus from the pleura, the blood and the serum of the enlarged joints. Its virulence was much attenuated, for injections into rabbits were only once successful in producing arthritis.—*La Riforma Medica*, June 29, 1904.

Congenital Serous Cyst of the Neck.—Latronche reports this case. The patient was a small child who had been left at the hospital, and consequently no history was obtainable. The tumor developed slowly without pain and without causing any functional trouble. On this account its exact beginning was unnoticed. It is on the right side of the neck and is now the size of a hen's egg. The skin over the growth is normal in color and temperature. The tumor is soft and clearly fluctuating. The fluctuation is entirely superficial. On pressing the growth, the beating of the carotid can be felt. The mobility is only partial, as the tumor adheres to the deep parts of the neck. The tumor is dull on percussion. Auscultation is negative. Since the entrance of the infant to the hospital, the tumor has increased in size, and now causes functional disorders. Breathing seems to be less easy, the child snores in its sleep, and it coughs and chokes while eating. Operation has not yet been performed.—*Journal de Médecine de Bordeaux*, July 10, 1904.

The Curative Value of Lumbar Puncture in Sydenham's Chorea.—G. B. Allaria believes that rachicentesis is a therapeutic procedure too little appreciated, which may quickly lessen the morbid movements, permitting better feeding and quiet sleep, and thus conducing to the rapid cure of the disease. He has treated twelve cases in this way. These he divides into two categories, those in which the fluid escaped under pressure, denoting an increased cerebrospinal pressure, which were benefited by the operation; and those in which there was no increased pressure, indicated by the escape of fluid slowly, by drops, which were not benefited. In one case the improvement was marked, movements being lessened on the day of puncture, and a cure accomplished in ten days. Two other cases were cured quite rapidly after the puncture. He considers the benefit to be due to the lessened cerebrospinal pressure from the removal of from 20 to 40 cm. of cerebrospinal fluid. This increase of pressure produces irritation of the cerebrum and causes the abnormal movements. He has observed no bad effects from the puncture, and has not found an anæsthetic necessary.—*Rivista di Clinica Pediatrica*, June, 1904.

Hypertrophic Congestions of the Kidney.—Le Dentu has had under his care a woman having a large tumor in the right hypochondriac region. It was at first thought to be a malignant growth of the kidney. There was no fever. An exploratory puncture was suggested. The needle penetrated into solid tissue. After this puncture, the kidney diminished in volume, and the patient gradually recovered. This case recalls one published by Terillon. This patient was a woman aged thirty-one years. She was the mother of two children. For several months she had suffered from pains in the right side. Her skin was pale. The diagnosis of floating kidney was made. The pains increased, simulating nephritic colic. In the right hypochondrium, a tumor was felt of the size of a large fist. There was no tuberculous history and no hæmaturia. The urine was normal. The left kidney was as low as the right but it was small and movable. The right kidney was in contact with the lower hepatic fossa, and was immovable. Attempts to return it to its normal position, were fruitless. Nevertheless, during the next few days, the tumor seemed to diminish in size, and it became slightly movable. On account of this improvement operation was delayed. In the absence of a clear antecedent history, it is always difficult to give the prognosis of a renal tumor. It is known that certain tumors disappear under the influence of rest or exploratory puncture. Especially must prognosis be guarded if the patient suffers from displacement of the kidney. A simple hypertrophic congestion might produce the phenomena above mentioned.—*Journal des Praticiens*, July 16, 1904.

Surgical Suggestions.

Treatment of Alveolar Abscess with Fistula.—C. C. Noble advises the application of trichloracetic acid through the opening in the gum. After two or three days the canal is thoroughly washed out with hydrogen peroxide and treatment repeated.

Wounds of the Pancreas.—In the treatment of wounds of the pancreas, Küttner recommends suture in preference to plugging; but care must be taken that the sutures are not inserted so deeply as to wound the superior mesenteric artery.—*Beiträge zur klinischen Chirurgie.*

Fistula in Ano.—In certain tuberculous patients, when anæsthesia and confinement to bed are undesirable, and when the sphincter is relaxed (as is usually the case in such patients), cure can be obtained by operating under cocaine. If, however, anæsthesia is desirable, a more rapid and certain cure can be obtained, in the subtegumentary variety of fistula, by dissecting it out rather than by incising it.—Walter C. Wood.

In cases of old fistulæ, by carefully dissecting out the scar tissue, and suturing the wound from the bottom, satisfactory results had been obtained, and the period of confinement is materially shortened. By injecting a strong solution of methylene blue the fistulous tracks can more easily be followed out than when a probe or fine bougie is used.—J. P. Warbasse.

Removing Needles from the Tissues by the Aid of the X-rays.—An original method of accomplishing this frequently necessary surgical operation is described by E. W. Shenton in *Medical Electricity and Radiology*. The needle having first been definitely located by means of the *x*-ray, the limb is turned about in such a fashion as to foreshorten the needle until it appears as a single point. At a point upon the skin corresponding with this end of the needle is placed an ink spot, upon the opposite side is placed another. It will be readily seen that a line joining these two points will pass through the needle in a line parallel with its axis. If the tissue now be taken between the thumb and finger and pressure be exerted upon the two ink spots, the needle will be caused to move toward the surface corresponding with its sharper end. The tissues are compressed slowly and evenly, and time is allowed between each pressure for them to regain their natural position. The needle will always travel toward the surface contiguous to its sharper end, and where this is too blunt to penetrate the integument, a prick with a scalpel will generally suffice.

Remove Neoplasms.—If possible, neoplasms should be removed wherever situated and whatever their apparent nature. There is always some uncertainty in the diagnosis, and benign tumors may become malignant.—Richardson.

Angioneurotic Erythema.—Joseph C. Bloodgood reports three cases in which neurectomy was performed with apparent permanent relief.

Pyorrhœa Alveolaris.—Hermann Printz advises the use of strong organic silver salts, applied by means of a platinum loop.

Warnings after Accidents.—Never forget to warn your patient that a Colles' fracture, even when treated with the greatest care, leaves some deformity; and that there may be loss of power in the deltoid after dislocation of the shoulder.—Fenwick.

Gastric Ulcers Treated by Excision.—Sinclair White reports five cases of gastric ulcer with evidences of perforation treated by excision. In each case the rupture was in the anterior wall of the stomach and the stomach contents reached the pelvis. A glass drainage-tube was passed into the pelvis through a small suprapubic incision and kept in for two or three days. Three patients recovered, and two died some time after operation as the result of ulceration of the mucous membranes along the line of suture.—*British Medical Journal.*

Book Reviews.

Der Einfluss von Boden und Haus auf die Haufigkeit des Krebses, nach Detail-untersuchungen in Bayern. Von Dr. Karl Kolb. Munich: J. F. Lehmann, 1904.

In a number of localities cancerous diseases have appeared with such frequency as to assume an almost endemic character. This frequency has been attributed to geological and physical characters of the soil and climate, and in this volume Kolb has studied in detail the conditions as found in a certain number of selected districts in Bavaria, where, among the foot-hills to the north of the Alps, cancer has been particularly prevalent and attended with a high mortality. The influence of the soil on the occurrence of cancer is dependent on the amount of moisture present. The death rate is increased in tertiary sections where the soil is clayey and more or less impervious, but is lessened where the soil is gravelly and porous. Chemical constituents have an important bearing on the case, the presence of clay favoring that of chalk, diminishing the liability to the production of cancer. Organic materials in the soil are also of importance. The upper layers, however, seem to be the ones which exert the most influence. The bearing of the habitation on the prevalence of cancer is entirely dependent on the soil on which it is built, and in certain instances it was found that particular groups of buildings presented a death rate six times that of the immediate neighborhood. The author believes that his observations, although necessarily incomplete, point to microorganisms as the cause of cancer. The probability is that they are widely distributed saprophytes, which in only comparatively rare instances find the proper host and conditions for a symbiotic existence. They are chiefly found in the soil of damp cellars, from which they find their way, in the form of dust, into the human organism. In the latter, the main points of entry are the alimentary tract and the female genitalia. Although the author describes the conditions as believed to exist in a particular locality, there are many suggestive points applicable to other regions.

Vorlesungen über den Bau der nervösen Zentralorgane des Menschen und der Tiere. Von Prof. Dr. Ludwig Edinger. Leipsic: F. C. W. Vogel, 1904.

Edinger's lectures are to students of neurology what Gray's Anatomy is to beginners in medicine. They are the most reliable source of information concerning the architecture and anatomy of the nervous system in any language. The fact that a highly technical treatise should have passed through seven editions in less than twenty years, shows that its worth has been appreciated. The text of the present edition has been completely rewritten and the illustrations materially increased in number. The volume is still cast in the form of lectures. Part I is taken up with a brief retrospect of the history and methods of investigating the central nervous system, the ganglion cells and nerves, fundamental conceptions, the construction of the nervous system from a physiological standpoint, and remarks on peripheral innervation. In Part II are discussed the development of the brain, the contour of the human brain, the peripheral nerves, roots, and spinal ganglia. The spinal cord has four lectures devoted to it, and no one can read the masterly presentation of the subject without admiring the author's grasp of the subject and his capacity for conveying it. The remaining lectures are devoted to the origin of the cranial nerves, to the oblongata, pons, and brain stem, the hind-brain, mid-brain, and fore-brain. The cortex of the brain is considered in a separate lecture, and here much new material has been added. In the last lecture a general survey of the subject is attempted. It is a work of supererogation to recommend this most valuable and entirely trustworthy work. It is essential to all students of neurology.

Elements of General Radiotherapy for Practitioners. By Dr. Leopold Freund Vienna. Translated by G. H. Lancashire, M.D., Brux, M.R.C.S. Eng.; L.R.C.P. Lond.; Assistant Physician to the Manchester and Salford Hospital for Skin Diseases. With 107 Illustrations in the Text and one Frontispiece. New York: Rebman Company, 1904.

Freund's original work was well received. It was an account of what the writer had observed, worked out, and found practical. The author was a pioneer in his line, and as such was looked to for guidance in a new realm of science. He wrote in the rational manner of frequent and free quotation from the writings of others, commenting upon and criticising their deductions. Much has been accomplished in the matter of history-making in ray therapy since Freund's work appeared. While advance in one direction has been in a measure suggested by the "Notes on Instrumentation," from the pen of Dr Clarence A. Wright, published in connection with the translation, the actual work of recent years of treatment is not sufficiently represented. The translator's work has been well done and with evident great care. The table of contents includes Elements of electricity; Treatment with high-frequency currents, Treatment with X-rays Becquerel rays, Treatment with heat and light rays, a short appendix and list of authors. The illustrations are chiefly of instruments and apparatus. The printer has made a book light in weight. The subject matter is in no wise so to be considered, but, in the rapid strides of the subject some of it must be considered as inadequately representing the present status. The work will always attract attention as representing Freund's personal exploits and findings.

Roentgen Ray Diagnosis and Therapy. By Carl Beck, M.D., Professor of Surgery at the New York Post-Graduate Medical School and Hospital; Visiting Surgeon to St. Mark's Hospital and the German Poliklinik. With 322 illustrations in the text. New York and London: D. Appleton & Company, 1904.

This book fairly represents a large amount of literature that has appeared in recent times. The subject being so new and important it is quite necessary that learners should not acquire knowledge which they will be forced to forget and learn anew. Notwithstanding the statement in the preface concerning the prime importance of a knowledge of the principles of construction and operation of the implements used, out of a total of 460 pages, only seventeen are devoted to a consideration of this important subject of apparatus. We think the utility of the work to the general practitioner would have been enhanced had the author devoted more space to this subject.

Three hundred and thirty odd pages are given to the subject of diagnosis. In these fully one-half of the available space is occupied by shadow pictures. This we cannot but regard as a blemish, for it is now generally considered that whatever diagnostic value there is in a skiagraph lies in the negative and is lost in reproduction, especially in so poor a medium as a half tone. In the short section on the therapeutic applications of the rays, mention is accorded the different conditions in which the ray has been demonstrated as of undoubted value. The illustrations here are less numerous and of better quality than in other parts of the book. They are mainly of cases of cancer that have occurred in the practice of the author.

Although the book is intended only as a treatise on the *x*-ray, some space is accorded a consideration of the Becquerel rays, radium, the Finsen light, and high-frequency currents. Concerning the Finsen light, the author says that "we know that the ultraviolet rays are composed of the blue, violet, indigo, and ultraviolet portions of the spectrum, while the nature of the Röntgen rays is still x, that is unknown." Again, referring to the Finsen method, he says that "all in all, this mode of treatment cannot, ingenious as it is in its present state, compete with the Röntgen method." While this is in a way true, we do not think any comparison should be made between the methods. They are separate and apart, and anyone who has made the subject a matter of study, or who has seen the Lysinstitut at Copenhagen, cannot speak disparagingly of the Finsen method.

In the present state of our knowledge regarding radiodiagnosis and radiotherapy, any contribution on the subject is to be welcomed, especially from such an original worker and acknowledged authority as is the author of this book. We have pointed out some of what seem to us to be weak points in the work—the good there is in it will speak for itself. The beginner cannot go far astray with the author of this really excellent treatise as his guide.

The Extra Pharmacopœia. Revised by W. Harrison Martindale, Ph.D., F.C.S., and W. Wynn Westcott, D.P.H., H.M.'s, Coroner for Northeast London. Eleventh edition. London: H. K. Lewis, 1904.

The originator of this unique and most useful little book has died since the publication of the tenth edition, but the work of revision has been carried on by his son in coöperation with Dr. Westcott, a coadjutor in the work since its inception in 1883. More than three hundred new titles have been added, to make room for which a number of the older preparations were dropped. An entire new section, entitled "Radiology," has been added; this includes a discussion of radium, *x*-rays, the Finsen light, the high-frequency current, radiant heat, and reflected sunlight. There is little more to add concerning this new edition, except that the revisers have succeeded in maintaining the excellence of the work. We know of no more serviceable and more accurate therapeutic manual than this. It is of small size and readily portable, very complete in its treatment of drugs and their application, and accurate in statement—in short, an excellent book of ready reference in therapeutics.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventy-second Annual Meeting, Held at Oxford, July 26, 27, 28, and 29, 1904.

(Special Report to the MEDICAL RECORD.)

(Continued from page 278.)

SECTION OF MEDICINE.

Third Day—Friday, July 29.

Heart Disease in Pregnancy.—The first papers of the third session of the section were on the maternal heart in pregnancy and the management of cases of pregnancy complicated by heart disease and were communicated by Dr. J. MACKENZIE of Burnley and Dr. H. O. NICHOLSON of Edinburgh. The changes observed indicated impairment of the left ventricle and engorgement of the right side of the heart. Danger to be expected from conception would be indicated by evidence of failure of compensation, and from evidence of a degree of auricular paralysis associated with mitral stenosis. This diagnosis was founded on the occurrence of continuous irregularity of the pulse, a diastolic murmur without a presystolic murmur of the crescendo type, and the alteration of the jugular pulse from one where it was produced mainly by the auricle to one where there was only one wave and that synchronous with and due to the right ventricle.

Bradycardia.—Dr. G. A. GIBSON of Edinburgh read this paper, which was illustrated by tracings. In one case with a radial pulse rate of 26 there were for each beat three or four pulsations in the jugular vein indicating auricular contractions between successive ventricular beats. The most benefit in treatment he had obtained from drugs of the digitalis and strophanthus group, with graduated exercises.

Serum Treatment of Disease.—Dr. E. GOODALL introduced a discussion on this subject, limiting his remarks to antisera proper, antitoxic and antimicrobic, to be used in two kinds of cases—those of intoxication and those of infection. An historical account of serum treatment was given and shortly discussed in relation to the less amenable diseases, such as tuberculosis, pneumonia, and anthrax and in greater detail in regard to others. In regard to diphtheria the experience of the hospitals of the Metropolitan Asylums Board's fever hospitals was given. The education of the fatality first observed on the introduction of the antitoxin was shown as follows—before, the mortality in successive years was 59, 39, 30, 29, and after, it was 22, 17, 12, 11, and last year 9.6 per cent. of case mortality. In the tracheotomy cases before antitoxin there was a recovery of 29 per cent. only, since then there had been a recovery rate of 62 per cent., excluding a recovery rate of 82 per cent. of intubation cases. Since the introduction of antitoxin the number of paralysis cases had increased, but this was entirely among those brought under treatment at a late date, and many of whom it was to be assumed would have died in former days. Early antitoxic treatment greatly obviated the tendency to contract paralysis. The immense value of serum treatment in this disease was amply proved. In regard to tetanus, the spasms were a late effect and were comparable with the paralysis of diphtheria. Statistics went to show that every case of tetanus should be treated with antitoxin, especially the chronic cases, but it had to be admitted that the outlook was not promising.

In regard to snake-bite, reference was especially made to the need for multivalent sera. In regard to hay-fever, allusion was made to Dunbar's antitoxic serum and to some beneficial results which were obtained from its hypodermic injection; this, in fact, seemed to be the most efficacious remedy that had been brought forward. In regard to plague, the evidence seemed to be certainly in favor of the serum treatment. As to typhoid fever, it was very difficult to produce an immunizing serum. In a certain hospital in Paris in which serum was used thers was a mortality of 3 per cent., while in other hospital in which it was not used there was a mortality of 19 per cent. The need for recording the age of patients under treatment was strongly emphasized. The results were encouraging, but no more than that could be said. Antistreptococcic serum, an antimicrobic agent, had been used in many different conditions, especially in puerperal fever, but this condition was due to many causes, and it was not likely to do any good in sapræmic cases or in microbic, other than streptococcic, cases, besides this the serum should be for a particular strain of streptococcus. Erysipelas and plegmonous inflammation of the skin certainly seemed capable of amelioration by antistreptococcus serum. In reference to dysentery it was still doubtful whether it was a microbial or a toxic disease and its use was still problematical. The prophylactic use of sera was apparently applicable in diphtheria, it should be used in the case of tetanus in countries where it was epidemic. The suggestion had been made to use antistreptococcus prophylactically. Dosage and the question of standardization were discussed. The estimation of the standard of the minimal lethal dose seemed to be open to fallacious variation. Probably all standardization should be under the official supervision of the State. The earlier the treatment was undertaken the more likely a favorable result. The untoward effects of serum treatment, such as rashes and pains in the joints, were alluded to. There were probably no absolute contraindications of the serum treatment. Although serum therapy has won a great triumph in diphtheria, the same could not yet be said for other diseases.

Dr. C. J. MARTIN asked how far it was advisable to administer antitoxic sera intravenously. Reference was made to experiments on snake venom by Sir Thomas Fraser—an amount of toxin neutralized by a given amount of antivene *in vitro* was neutralized by the same amount if injected into a vein but required ten or twenty times the amount if injected into another part of the body, suggesting the slow absorbability of the antitoxin. If then there was need for hurry in treatment, antitoxin should be injected into a vein.

Dr. F. F. CAIGER limited his remarks to diphtheria and discussed the whole subject historically and generally. He had not had any very satisfactory results from multivalent sera in diphtheria. As to after-effects, they bore no relation to the antitoxic efficacy of the serum. He could give antitoxin in every case of diphtheria in a young child; in older patients he exercised some judgment in witholding it. Dr. Bulloch pointed out that while in the case of diphtheria and tetanus the poison produced was extracellular, in the case of other diseases the toxin was in combination with the proteid of the organism. Its solution in the latter case had been obtained in only the case of cholera and typhoid fever. Of other diseases in which immune body and complement were required to ensure the destruction of the organisms, the organisms involved were the common attackers of man, as for instance, the pyogenic cocci. In the last case there was not only no good reason for using the sera but there were even reasons for not using them. It was even likely that the immune body of man did not combine with the complement of the horse. The injection of serum might do harm by the complement being taken up by unattached immune bodies, leaving the bacteria unacted upon. Thus the therapeutic value of other than true antitoxic sera was doubtful. In the case of certain toxins the degree of protection was very slight, *e.g.* protection against more than three or four lethal doses of staphylococci could not be obtained. The method for the future would probably be vaccination of patients with the specific bacteria, so that they might themselves manufacture their own antitoxin.

SECTION OF OBSTETRICS AND GYNECOLOGY.

First Day—*Wednesday, July 27.*

THE President, Dr. F. H. Champneys (London), in opening the proceedings, welcomed Professor Olshausen (Berlin) and Prof. B. S. Schultze (Jena), who were present.

Treatment of Accidental Hemorrhage.—Sir A. B. MACAN, ex-Master of the Rotunda Hospital, Dublin, opened the discussion on this subject. He expressed his indebtedness to a paper on the subject by Dr. A. W. Holmes, which had appeared in the *American Journal of Obstetrics*, and said that, at the present time, there was no subject in obstetrics about which such opposite views prevailed as of the one under discussion; this was true, both of the more serious methods of treatment, as cæsarean section and accouchement forcé, and of the simple, as rupturing the membranes or plugging the vagina, and a really satisfactory method of treatment had yet to be found out. This, also, was the conclusion arrived at by Dr. Holmes in the paper already mentioned. He thought that the system of plugging the vagina and putting on a binder and perineal bandage was the most efficient method of treating all but the most severe cases.

The causes could be divided into (1) accident, (2) disease, and (3) failure in the mechanism of labor. All modern views agreed that disease was the most important cause. This might affect the placenta and membranes, or uterine wall, or might be a general blood disease, as scurvy or hæmophilia. As regarded the third cause, the abnormalities in the mechanism might be: (1) Bag of membranes persisting too long and pulling on placenta; (2) retraction ring rising too high in prolonged labor and causing diminution of the area of the placental site; (3) cord too short; (4) delay in delivery of head in breech presentation, the uterus contracting and so diminishing the placental site; (5) sudden escape of liquor amnii.

The conditions tending to arrest the hemorrhage naturally were: (1) Weakening of the heart's action; (2) increase in intrauterine tension from pressure of effused blood; (3) formation of thrombi. The causes of the hemorrhage remaining internal were: (1) Small amount; (2) the site of the bleeding being in the center of the placenta, the hemorrhage then goes on in concentric rings until the blood reaches the edge; (3) the position of the hemorrhage in regard to the os; (4) the tone of the uterus (5) the fetal head blocking the lower uterine segments. His view was that contraction of the uterus only arrested hemorrhage during the contraction and that retraction was necessary to arrest bleeding, the latter not occurring while the fœtus was in utero.

If the placenta came into the distensible zone between the internal os and the retraction ring, forming a slight degree of placenta prævia, it could not be reached with the finger, and so a differential diagnosis in these cases was impossible.

In internal hemorrhage a localized swelling of the uterine wall could sometimes be made out. In combined hemorrhage there were constitutional symptoms out of all proportion to the amount of blood lost.

The first indication was, if possible, to arrest hemorrhage without removing the child, and if that could not be done, then, second indication, we must empty the uterus. The third indication was to arrest postpartum hemorrhage. The fourth, to treat the resultant anæmia. He used plugging of the vagina and cervix with pressure on the abdomen by a tight binder to comply with the first indication. Herman Galabin and Holmes were against this. Smyly, during his masterhsip of the Rotunda, resuscitated plugging from the discredit into which it had fallen, but limited its use to cases in which the membranes had not ruptured. Pusefoy, a later master of the Rotunda, applied it to all cases.

Pusefoy advised placing the patient in the lithotomy position, using separate plugs of cotton wool soaked in perchloride solution, and applying a tight binder and a T-bandage; if the pains became vigorous he took off the perineal bandage and removed some of the plugs. He (Pusefoy) had treated forty-two cases in this way with two deaths. The last four masters of the Rotunda were firm believers in this method of treatment. If the hemorrhage could not be checked by this plan, he was entirely in favor of cæsarean section in preference to accouchement forcé. If dilatation of the cervix was decided on, he gave the preference to Trommel's modification of Bozzi's dilator, which had eight prongs instead of four.

Dr. GALABIN of Guy's Hospital, London, had met with two cases in which accidental hemorrhage was due to partial vesicular degeneration of the placenta associated with a living fœtus. He would hesitate to treat concealed accidental hemorrhage by plugging. He thought the danger of further hemorrhage and of shock was great in cæsarean section, and he would prefer to use Bozzi's dilator.

Dr. MUNRO KERR of Glasgow said that the statistics of the Glasgow Maternity Charity, showed twenty cases in three years.

The maternal mortality was 20 per cent.; and infantile 95 per cent. He believed in the method of treatment by plugging. Four extremely severe cases had been treated by accouchement forcé, and of these three died, two from postpartum hemorrhage; in such cases in the future he intended to do vaginal cæsarean section.

Professor BYERS of Belfast recognized two types: (1) Concealed; symptoms of bleeding with no blood appearing internally. He considered this the most serious complication of midwifery next to sepsis, as the uterine wall had lost all tonicity. He favored opening the abdomen in preference to accouchement forcé, having had disastrous results from the latter proceeding. (2) When some blood appeared externally; this was more favorable, as it showed the existence of some contractile power in the uterus. In these cases plugging gave the best results. Recent statistics of the mode of treatment at the Rotunda gave fifty-seven cases with one death. He also had experienced disastrous results from accouchement forcé.

Dr. JOHN CAMPBELL of Belfast packed the cervix as well as the vagina, using lithotomy position. Speculum and vulsella.

Dr. NICHOLSON of Edinburgh had found that the postpartum bleeding in these cases could be checked by packing with iodoform gauze soaked in adrenalin chloride solution.

The PRESIDENT would divide the cases into three classes, namely, those in which (1) nature will effect a cure. (2) Patient's life in imminent danger. (3) The case goes on all right if treated well, but may go wrong with bad treatment, and it was this last class of cases which could be best treated by plugging.

Dr. Macan, in closing the discussion, said he hoped that plugging would be extensively used in the slighter cases and the results reported.

Operation for Carcinoma Uteri in Germany.—Professor OLSHAUSEN of Berlin then read in English a paper on this subject. He said that those in favor of extensive abdominal operations for cancer were numerous in Germany and Austria, although himself and a few others favored the vaginal operations. On the question of removing glands, Mackenrodt removed all glands within reach; it was impossible to know which were affected. Glandular affection was usually late. It was impossible during operation to recognize infection of glands, for small ones were sometimes infected while enlarged ones were not. The removal of glands must involve removal of surrounding connective tissue, but operations like those which were carried out on the breast were quite impossible in this region. These operations on cases in which the growth extended beyond the uterus had a high mortality, and injuries to the urinary tract were very common, amounting to 39 per cent. He performed vaginal hysterectomy in 61 per cent. of the cases which came under his care. Up to 1903 (commencement of) he had operated on 671 cases with a mortality of

6 per cent. Since then he had operated on 137 cases with six deaths, or a mortality of nearly 4½ per cent. The statistics of 500 cases showed that at the end of two years after operation 78 per cent. were living; at the end of five years 30 per cent. Showing that more cases died between the end of the second and the end of the fifth year after operation than in the first two years. He held that the extensive abdominal operations lately advocated were not justified by the results, and thought that vaginal hysterectomy was the best surgical treatment for uterine cancer. Professor Olshausen was thanked for his paper, and this concluded the business of the sitting.

Second Day—Thursday, July 28.

Removal of Fibromyoma of Left Ovary 22½ Pounds in Weight.—Dr. J. Singleton Darling of Lurgan, Ireland, reported this case and showed the specimen.

Drs. Parslow of Birmingham, Fairbairn of London, and MacLean of Cardiff discussed the case, and all were of opinion that the tumor had the appearance rather of a fibroid of the broad ligament than of a true ovarian fibroma. A special committee of three members was formed to examine the specimen and report to the next meeting of the Section.

Two Cases of Urethrovaginal Fistula Treated by Operation.—Dr. F. J. McCann of London read this communication. The first case was delivered by forceps. Chronic retention of urine with dribbling from overflow followed. A slough separated, laying open the whole urethra and the base of the bladder. At the operation the bladder and urethral mucous membrane were separated from the vaginal over a considerable area, and the wall of the urethra and bladder united by catgut sutures. The bladder, however, was contracted and appeared to have lost all power; efforts were made to distend the bladder by fluid pressure, but incontinence persisted and patient now wears portable urinal. The same case followed version and craniotomy on aftercoming head, and a similar operation was completely successful.

The President said that he had found cases in which the bladder was contracted owing to the habit of very frequent micturition, and had successfully treated them by gentle fluid pressure of not more than a foot of water.

An Early Case of Chorion Epithelioma Following Hydatid Mole.—Dr. Smallwood Savage of Birmingham reported this case. There was a history of irregular hemorrhage for nine weeks, wasting, dyspnœa, and pain. On examination uterus reached to umbilical, the finger could be passed through os and felt soft, doughy mass in cavity. An anæsthetic was given and a large amount of hydatid mole removed. Two months later profuse hemorrhage, producing faintness, set in, and a fortnight later vaginal hysterectomy was performed. Five months had now elapsed since operation and the patient was in good health. The specimen, together with photographs and lantern slides of microscopical sections, were shown; the growth was seen to occupy an area the size of a sixpence on the posterior wall midway between cervix and fundus; it was wedge-shaped, with its apex to the peritoneal aspect. The sections showed villi, syncytium, and Langham's polyhedral cells.

A Case of Deciduoma Malignum.—Mr. Christopher Martin of Birmingham reported this case. The patient was fifty years of age and there had been no pregnancy for six years; severe uterine hemorrhage set in and the uterus was removed. Some weeks later hæmoptysis set in and patient died with secondary growth in the lungs. Microscopical section proved that the growth had all the characteristics of deciduoma malignum. The sections, together with the uterus, were shown, also a lantern demonstration of the photo-micrographs.

A Case of Chorion Epithelioma.—Dr. Thomas Wilson of Birmingham reported this case. The patient, a single woman, had been delivered of a hydatid mole some time previously, and when she was admitted to hospital she presented all the signs of advanced malignant disease of the pelvis and lower abdomen, and operation was considered to be out of the question. She died soon afterward and post-mortem examination showed a malignant growth of the uterus, which had passed through the uterine wall and invaded bladder and intestine. Microscopical sections showed the growth to be a typical chorion epithelioma. A lantern slide demonstration of the microscopical appearances in this case was also given.

Both Dr. Martin's and Dr. Wilson's cases were alike in the fact that the intrauterine growth was extremely soft and almost exactly resembled blood clot.

Suggestions for the Prevention of Puerperal Infection in Private Practice.—Dr. Byers of Belfast read a paper with this title. He pointed out that while the mortality from sepsis in lying-in hospitals had been almost banished, the mortality in private practice in the United Kingdom, as shown by the Registrar General's returns, was still almost as high as before the introduction of antiseptic treatment. The researches of modern observers had shown that there were no pathogenic organisms in the uterus and vaginal canal, but that they swarmed on the labia and hymen. The most potent cause of puerperal sepsis was vaginal examination, and, in his opinion, the best way of prevention was to dispense with vaginal examination almost entirely. The majority of labors might be perfectly satisfactorily conducted by abdominal examination alone, and he strongly advocated that more stress should be laid on the importance of abdominal palpation in the teaching of both medical students and midwives. When vaginal examination was absolutely necessary, the hand should be carefully sterilized with soap and water and perchloride solution. No lubricant should be used. He laid particular stress on the importance of avoiding contamination of the right hand, with which he made vaginal examination, after it had been cleansed, and advised that the labia should be cleansed with soap and water and perchloride, and afterward carefully separated by the fingers of the left hand before the right forefinger was introduced.

A paper by Dr. Munro Kerr of Glasgow, on "Cancer of the Cervix Complicating Pregnancy," concluded the business of the day.

Third Day—Friday, July 29.

A Further Contribution toward the Study of the Natural History of Tubal Gestation.—Dr. Addinsell of London read a paper with this title. He said the important question in those cases was the one as to whether it was better to operate at once or to wait. He narrated fifteen cases, four of which were operated on and recovered, and the remaining eleven recovered without operation. In the latter cases the subsequent history did not show that there was any later trouble from the effused blood. The patients should be kept in bed from the first onset of signs of hemorrhage. He drew attention to the danger of confusing these cases with cases of ordinary abortion. He laid down the following rules for treatment: (1) If the patient rallied from the primary shock—wait. (2) If there was a further attack of hemorrhage—operate. (3) If the pregnancy was diagnosed before there were signs of rupture—operate. (4) If hæmatocele had formed—wait. (5) If hæmatocele became infected—open from the vagina.

The So-called Ovarian Pain; Its Causes and Treatment.—Dr. Herman of London then introduced the discussion on this subject. He said this pain was felt at a spot about two inches anterior and internal to the anterior superior iliac spine, and pain on pressure there was thought to be due to duct pressure on the ovary. He had, however, by post-mortem experiments satisfied himself that the ovary was not actually pressed on when pressure was made at this spot, and the idea that pain was due to the ovary had been given up because pain in exactly the same spot occurred in hysterical men. He would divide the pain as follows:

1. Peritoneal pain. This was felt at the inflamed spot only and not in the back.

2. Reflected pain. This spot was in the area supplied by the tenth dorsal nerve, and disease of any of the genital organs might cause pain which would be referred to this spot. In this case the pain would also be felt in the loin and over the hip and the skin would be tender. Certain causes of this pain were alcohol, incomplete sexual intercourse, and recurring severe dysmenorrhœa.

3. Neurasthenia. This might be brought about by anæmia, tuberculosis, influenza, or by mental causes. The perplexing cases were those in which pain from organic diseases of the ovary was present in neurasthenic patients, and it was important to remember that the neurasthenic condition might cause the pain to persist even after the cause was removed. The pain was more common on the left side; the explanation of this must be that the left side of the body was weaker and less resistant to pain than the right; as in other diseases, as cancer of the cervix or retroflexion, in which both sides were equally affected by the disease, this left-sided pain was more common.

4. Hysteria. Modern views of neurologists regarded this as a disease of the cerebral cortex. It was characteristic of hysterical pain that it did not follow the anatomical distributions of the nerves, but it affected those parts which the patient regarded as natural divisions of the body, as the foot or the hand. In neurasthenic pain local treatment did no harm, but in hysterical pain local treatment was the worst possible treatment, as it fixed patient's attention on her condition. He next discussed the conditions of the ovary which have been said to be the cause of the so-called ovarian pain. These were sclerocystic disease and cirrhosis of the ovary. The first condition was, in his experience, usually associated with fibroid tumor of the uterus. As regarded the second, he did not believe that shrunken ovaries were generally painful, as alleged by Pozzi. Bland Sutton had pointed out that in so-called cirrhotic ovaries there was no evidence of chronic inflammatory change as in cirrhosis of the liver and kidneys. Cirrhosis of the ovary was not thought to be a disease until it became the custom to open the abdomens of women who had this pain. It had been stated that the cirrhotic ovary was the final stage of the sclerocystic, but there was no evidence adduced to prove this.

The reflected pain due to persistent severe dysmenorrhœa was the only one which could be cured by removing the ovaries. The neurasthenic pain should be treated by rest, food, and sleep, and the removal of the conditions which brought about the neurasthenic condition. As regarded treatment of hysterical pain, suggestion and moral treatment should be used. Operations to carry out suggestion were condemned. If the patient remained in the sorroundings where the condition began it would recur. Speaking generally, no conclusion as to surgical treatment could be drawn unless the cases were observed for a long time. He had used ignipuncture of the ovary; there was always immediate relief, but later the pains returned.

Mr. Bowreman Jessett of London said that pain in the region mentioned was sometimes due to disease of the appendix. He thought that sometimes acute pain was caused by sclerocystic disease and could be removed by excising the diseased portions of the ovary.

Dr. John Campbell of Belfast considered that the pain was sometimes due to a varicose condition of the veins of the broad ligament, and that this was due to a sedentary life and chronic constipation.

Dr. Herbert Snow of London thought that two important causes of the pain were the wearing of corsets and neglect of the bowels, the latter explaining the more frequent occurrence of the pain on the left side. He considered that a common cause of neurasthenia was endocervicitis.

Dr. Stanley Boyd of London pointed out how variable was the occurrence of pain in retroflexion and other pelvic diseases. She had found a varicose condition of the veins of the broad ligament in these cases. The only satisfactory test of the result of operative treatment was—Could the patient return to her usual work afterward?

Dr. MacLean of Cardiff distinguished two types of patients; the florid type, who were generally single, or, if married, sterile, and liked to be considered invalids, and the anæmic type. He had found that resection of the ovaries was often a failure.

Dr. Heywood Smith of London thought that if the pain of dysmenorrhœa began to be felt in the interval, that was a sign that some organic change was taking place in the ovary.

Dr. Cuthbert Lockyer of London had examined microscopically numerous pairs of ovaries removed for chronic pain, and had come to the conclusion, from the pathological point of view, that it was impossible to diagnose ovaries which had produced pain; and many of those he had examined contained follicles and stroma in such a condition that they would have been fully capable of carrying on their functions.

Dr. Inglis Parsons of London thought that sclerocystic disease was sometimes a cause of pain.

Dr. Rabagliati of Bradford thought that the pain was often of a gouty or rheumatic character, and that many of the subjects of it were edentulous and dyspeptic and in the habit of taking meals of tea and bread and butter at too frequent intervals. He advocated rest in bed and regulated exercises, which might be carried out by the patient herself after instruction.

Dr. Fothergill of Manchester called attention to cases in which the pain was associated with temporary enlargement of the ovary, and considered this was due to ovulation, which in his opinion often occurred independently of menstruation.

Dr. Hellier of Leeds advised the examination of each case under an anæsthetic.

Dr. Byers of Belfast would not open the abdomen unless something definite could be felt.

Dr. Forbes-Ross of London thought that there was no analogy between varicose veins in the broad ligament and varicocele in the male, because in the latter case the disease was due to the veins being unsupported.

Sir Arthur Macan of Dublin preferred the name iliac pain, and considered that left iliac pain was often due to disease of the cervix. He drew attention to the marked difference between the results of removing one ovary or both, the latter being so much more serious as regarded after-effects. He had no belief in partial operations on the ovary, as it was impossible to say whether all the diseased tissue had been removed.

Dr. Herman, in closing the discussion, said he doubted whether varix of the broad ligament was a cause of pain, as Pearse Gould had shown that in cases of varicocele in the male the pain was not due to the dilated veins. He had given up ignipuncture and resection of the ovary.

A paper by Dr. MacLean of Cardiff, on "Some Cases of Ectopic Gestation," concluded the business of the meeting.

Section of Surgery.

First Day—Wednesday, July 27.

The Surgical Section met in the Clarendon Laboratory, with a full attendance.

Address of the Chairman.—Horatio P. Symonds, F.R.C.S., Edinburgh, made the opening address, in which he reviewed Listerism and described his experiences in the hospitals at the time of the Franco-German war, and alluded to the first cumbersome methods of antiseptic treatment. He also mentioned the possible advantages of an open-air plan of surgical treatment.

The Present Aspects of Asepsis and Antisepsis.—Mr. P. F. Burghard, in the absence of Mr. W. Watson Cheyne, opened the general discussion on this subject. He read a paper reviewing the present status of surgical treatment,

and said that the modern standard of result was higher than the mere question of recovery. There must be no redness, swelling, or discharge from wounds after operations. He recognized the fact that absolute sterility was practically impossible, and that there were differences of opinion as to the best method of attaining approximate perfection, but not as to the principle involved. The speaker mentioned the usual three channels of infection: (1) The skin of the patient and surgeon; (2) the instruments, sponges, and ligature material, and (3) the air. He considered boiling the most applicable means of sterilizing instruments, etc., and rejected steam, except for trays, basins, etc. As to the use of antiseptics, they all took time and must have good access. They could not, moreover, be used in very strong solutions, but the speaker had had good results with weak solutions used in connection with aseptic methods. The ideal air-tight sterilized operating room was too complicated and was a practical impossibility. The use of antiseptics was a practical necessity on account of the danger of infection from airborne microorganisms. The method in use in King's College Hospital was then described, and the disinfection of the hands was discussed. In the opinion of the speaker, chemical disinfection of the hands was a practical necessity, and he had not found the use of gloves convenient or desirable on account of interference with palpation. He always used prepared and disinfected sponges and had never seen reason to regret such use. He also used certain sponges repeatedly. His dressings were usually moist and antiseptic, made so with 1-2000 sublimate or with the cyanide of zinc and mercury.

Sterilization of the Hands.—Mr. Leedham-Green of Birmingham followed Mr. Burghard with a paper which treated the matter largely from the bacteriological point of view. He had made an extensive series of experiments which seemed to prove that a bacteriological sterilization of the hands was a practical impossibility, no matter what method was employed. The germicidal power of alcohol was emphasized, and the excellence of the soft-soap-alcohol-sublimate method for the hands was insisted upon. Some of the newer and much used methods were condemned as being inferior to this.

Mr. G. Barling considered the hands the chief source of infection and the air the next in importance. In his experience, catgut should be prepared under the supervision of the operator himself, since that prepared by the manufacturers has not been found bacteriologically trustworthy. He called attention to the great bacteriological difference between the hand at the beginning and at the end of an operation, and stated that he placed his chief reliance on aseptic methods of operating, on keeping the wounds free from blood, and free from post-operative mechanical disturbances.

Mr. H. Stiles of Edinburgh emphasized the need of thoroughness, no matter what plan was adhered to. He devoted much attention to his assistants, and believed in being gentle in preparing the skin. He advocated the use of a mixture of lysol, green soap, and alcohol for the operative field, and did not fear infection from the air. He reported one hundred operative cases of hernia in children in which no infection occurred and in which practically no dressing was used. He used no antiseptic solution during operation, liked the use of superheated steam as a sterilizer, and preferred not to allow his house surgeon to do dressings.

Mr. R. Montserrat of Liverpool mentioned the fact that some regions required much more effort in order to secure sterility than others, and remarked that he was a thorough believer in gloves of which he used rather thick ones. He also advocated the flushing of wounds with saline solution.

Mr. G. Hamilton of Liverpool spoke in favor of simplicity and said that he had his assistants wear gloves though he himself did not do so. He had found the permanganate-oxalic method for the hand to be very reliable and he further advised that the number of assistants be kept down as much as possible.

Mr. J. Bush of Bristol described some personal methods. He did not like washing wounds with antiseptic solutions, but used moist antiseptic dressings.

Dr. Rodman of Philadelphia thought that it was easy to get surface sterility on the hands, but that this was not easy to maintain. He described the chlorinated lime soda method of hand-cleansing and characterized it as very severe. He was a thorough believer in the use of rubber gloves and saw no valid objection to them. He emphasized the powers of alcohol, and believed in flushing the wound at the end of an operation.

Mr. C. W. Cathcart of Edinburgh said that our sterilizing method must be simple and must afford the greatest good to the greatest number. He did not see the necessity of restricting too rigidly the number of spectators, but insisted on observance of details in field of operation. He saw no objection to the flushing of wounds with a 1-2000 sublimate solution.

Professor Macewen of Glasgow put himself down in favor of aseptic surgery. He used a 1-20 carbolic solution with glycerin for the hands after the usual scrubbing, and used gloves in some septic cases. He aimed at keeping the wound dry and used gauze swabs, not sponges.

Mr. Burghard, in closing, said that he did not place too much confidence in apparently discouraging bacteriological results. The actual results were too good for us to be thus downcast. Care and attention to detail were what produced good results, and he agreed that simplicity was very important. He not did find gloves satisfactory and got good results without them.

Cysts of the Neck.—Mr. G. H. Edington of Glasgow then read a paper on median cysts of the neck. He said that he divided such cysts into four classes, thyroglossal, ranula, dermoid, and sebaceous. He detailed a number of his own cases and showed a series of photographs.

A short discussion followed and the meeting then adjourned for the day.

Hysterectomy.—Mr. Bland-Sutton of London delivered an address on this subject, devoting most of his time to indications and plan of operation. Cancer was, of course, of the first importance, and the earliest operations, which were by the abdominal route, were failures. The introduction of vaginal hysterectomy marked a great advance, but it soon became evident that, in cases of malignant disease, the remote results of the operation were not good. The choice of operation depended to a considerable extent on the localization of the disease, and the fact that primary cancer of the fallopian tubes might occur and that it simulated cancer of the body of the uterus must be remembered. Operative treatment for such conditions did not give good results, but statistics were improving. He also called attention to deciduoma malignum as a disease occasionally requiring hysterectomy, and mentioned Teacher's collection of 188 cases in which he believed that the efficacy of the operation was sometimes shown. Fibroids and also sarcoma were other important conditions for which hysterectomy might be required. The speaker emphasized the fact that operations for fibroids might be extremely serious, especially in the case of large soft growths. He did not believe that fibroids ever became sarcomatous, such supposed instances being in his opinion malignant from the start. Hemorrhage, septic inflammation, and impacted fibroids were conditions which might require hysterectomy. Aseptic ligature and intraperitoneal treatment of the stumps were two important advances, but the question of panhysterectomy *versus* supravaginal amputation was still somewhat *sub judice*. The ideal method was enucleation, but this was possible in only 10 per cent. of all cases, and it offered no guarantee of continued immunity. However, the matter might often be placed before the

patient fully, and she could be left free to decide what she cared to have done. The speaker liked supravaginal operation for fibroids because it left the vaginal vault almost normal and diminished danger to the ureters. This latter matter was important, for in 152 panhysterectomies, at the Johns Hopkins Hospital, there were nineteen instances of injury to the ureters. Supravaginal operation was not so useful when the cervix was large, soft, or septic. He did not think that the remnant of the cervix was specially prone to the development of carcinoma. Saving the ovaries might be valuable for the patient, and leaving even a small portion was of advantage before the age of forty years, but afterward of no great importance. In about 20 per cent. of his cases he left one or both ovaries. There was a notable parallelism between the ovaries and the thyroid gland in both of which organs cancer might occur after forty, in the period of involution of the organs. A condition of diffuse adenomyama strongly simulated carcinoma and might demand hysterectomy. Two other conditions to be noted were acute sepsis and diffuse fibrosis, following sepsis. The speaker emphasized the fact that there was no need of sentiment in regard to the uterus, and that it should be treated in the same way as any other organ when it required surgical intervention.

Retroperitoneal Neoplasms.—Mr. Alban Doran reported a remarkable case of successful removal of a very large fibrous retroperitoneal growth, weighing thirty pounds, and he made some remarks upon the occurrence of such tumors. He designated his case one of fibromyoma of the mesentery. He exhibited the specimen and said that with such cases the mortality was of necessity high, and the technique difficult. In a large majority of cases, a diagnosis of ovarian cyst had been made. A point which would assist the diagnosis was the fact that over these tumors the resonance was likely to be irregularly dull and tympanitic in patches. In this case the patient was put on a course of strychnine for a week before the operation, and hot saline solution was used in the abdomen at its close.

Mr. Lockyer reported two cases, one, a large cystic fibromyoma removed without hysterectomy, with recurrence in two and a half years, when abdominal panhysterectomy was done; and another case in which panhysterectomy was done for menorrhagia with abdominal tumor. He believed that myomectomy was advisable in cases of true cervical fibroids.

Treatment of Uterine Fibroids.—Mr. Shaw-Mackenzie of London spoke in reference to medicinal and minor operative means of treating fibroids, and mentioned the usual drugs which were said to be useful. He mentioned benzoate of mercury as having a marked hæmastatic action.

Uterine Cancer.—Mr. Stanmore-Bishop of Manchester reported 107 cases of malignant uterine disease from 1893 to 1899, of which five were now living; and seventy from 1899 to 1902, of which twelve were free from disease up to the present. This indicated progress, in his mind. He agreed that even without cure relief might be afforded for a year or so in cases of malignant disease. Nearly all his patients had been operated upon by the vaginal method, which he preferred. He thought it possible for fibromata to become sarcomatous. Of the abdominal methods he preferred panhysterectomy to supravaginal amputation.

Dr. Galabin of London said that he preferred the operation by the vaginal route in cancer of the cervix, and had sometimes done it for disease of the fundus. In one case of great vaginal narrowing he made an accessory iliac incision with gratifying result. Hysterotomy was applicable to a few cases of uterine fibroids. He always decided on panhysterectomy if there was any suspicion of disease in the cervix.

Dr. Murdoch-Cameron stated his disbelief in any medicinal or electric treatment of fibroids. He mentioned a case in which he had found it advantageous to use an elastic ligature on the cervix before he could gain access to the uterine arteries.

Dr. Stanley-Boyd thought that it was desirable to keep the cervix, when possible, so as not to interfere too much with the pelvic floor, but in the presence of cancer he believed in very radical operations.

Dr. Scharlieb preferred panhysterectomy because it is more radical and may therefore obviate later trouble.

Mr. Bland Sutton, in closing, emphasized the unanimity of those present in regard to the indications for operative treatment, and said that he did not wish to be considered as in favor of any particular method.

Intravesical Separation of Urine.—Mr. Bickersteth then read a short paper on this subject, and showed some apparatus and specimens. The method shown was that by means of an instrument which divided the bladder by a longitudinal rubber dam into two chambers, and the speaker noted some very satisfactory results in diagnosis. He said, also, that he considered the character of the flow of great importance, as well as the urinary ingredients. He had found the methylene blue method very good with the apparatus when one kidney was not functionating.

This was followed by a paper, by Mr. A. H. Tubby of London, on "Muscle Grafting in Paralysis of the Serratus Magnus," with some cases. There was a short discussion, after which the Section adjourned for the day.

In the afternoon, at the Radcliffe Infirmary, a number of short papers were read and some clinical demonstrations were given.

Third Day—Friday, July 29.

This morning the interests of the Surgical Section were divided between the regular meeting and the address on "Chloroform" in the Hall of Balliol College, given by Sir Victor Horsley. In the regular meeting there was an extremely busy morning.

Hepatic Drainage.—Dr. Deaver of Philadelphia read this paper, using the term to include drainage of the biliary tract. He enunciated the infective theory of inflammatory processes in the biliary apparatus, and noted the fact that some infections were caused by the passage of the bacillus coli communis through visceral walls into various structures. Cirrhosis of the gall-bladder was occasionally due to ascending infection with one of several varieties of bacteria. The speaker then described the pathological appearances of the gall-bladder and liver in case of partial or complete common duct obstruction, and went on to the question of the time of operation. He agreed with Mayo Robson, that as soon as gallstones gave rise to serious trouble an operation should be done. He considered cholecystostomy indicated in acute infections, in chronic pancreatitis, and in certain other chronic conditions, and cholecystectomy only in chronic obstruction with ulceration and thickening of the bladder, in gangrene, and in cancer. As a point in operative technique, he recommended dissecting away the gall-bladder from the neck upward, after having secured the cystic artery. Most cases of gall-bladder surgery did well when the operation was performed in time. The question was largely in the hands of the general practitioner, who should make an early diagnosis and then call the surgeon. In conclusion, the speaker declared that inflammatory lesions of the biliary apparatus were of infective origin, that the complications influenced the mortality, that prolonged drainage was the salvation of infected cases, and that hepatotomy was only useful in the presence of abscess.

Mr. Jordan Lloyd said that he thought some gall-bladders ought to be removed because strictures might exist even after the disappearance of the stones. He agreed that excision should begin at the neck, and thought accuracy of diagnosis was not so great as it might be.

Dr. Deaver, in closing, said that he thought that a diagnosis could usually, in his opinion, be made with sufficient accuracy to warrant operation.

Carcinoma of the Mammary Gland.—Dr. RODMAN of Philadelphia then read a paper on this subject. He emphasized the futility of incomplete operation, and offered the following conclusions as indicating his position on the matter: (1) Cancer is increasing in frequency. (2) The young are bad subjects, partly on account of their active lymphatic circulation. (3) Early diagnosis and early operation are necessary. (4) When in doubt be ready to do what is radical. (5) The prognosis is worse when the growth originates in the sternal half of the gland. (6) The sound skin should be removed freely. (7) The pectorals should always be removed, and there are no bad effects from this. (8) Remove the supraclavicular glands. (9) There is no special danger in wounds of the axillary vein, the sheath of which should be removed. (10) Always use drainage. (11) An interval of five years should be allowed before claiming a cure. (12) Twenty-one surgeons and over six hundred cases give operative mortality of nine-tenths of one per cent. (13) General practitioners must be induced to make earlier diagnosis, and so avoid internal metastases. The speaker had had excellent functional results after the most extensive operations, and reported some remarkable figures after three and five-year intervals.

Certain Defects in the Usual Operation for Mammary Cancer.—Mr. W. S. HANDLEY of London read a paper with this title. His main point was that the cancerous advance was along the deep fascia in all directions, and that consequently the removal ought to be just as far downward in the abdomen as upward. He did not think that spread of the disease was so likely to occur in the skin. He suggested a modified S-shaped incision, so planned as to extirpate more of the fascia.

Mr. STILES said that he did not think that English surgeons were, as a rule, radical enough, and believed that the good ultimate results in America were due to the extensive operations which were done. He always removed both pectorals, dividing them at their origin, and treated the arm in the abducted position. He agreed that the sheath of the vein should be removed.

Mr. HAMILTON of Liverpool adopted a somewhat less radical operation and saw most of his recurrences in the axilla.

Mr. MONTSERRAT of Liverpool advocated radical operation and removal of the pectorals.

Mr. CHILDE of Southsea insisted on removal of pectorals, and had not had to do skin grafting operations.

Dr. Rodman, in closing, insisted that it was impossible to clear the axilla and Mohrenheim's fossa properly without removal of the pectorals, and he thought removal of the venous sheath extremely desirable.

Freyer's Prostatic Operation.—Mr. W. T. WALKER described and illustrated with lantern slides the anatomy of Freyer's prostatic operation. He went into the histological structure of the capsule of the gland, and made some remarks on the relations of the urethra.

Mr. P. J. FREYER then reported a series of operations by enucleation upon the enlarged prostate. His oldest patient was eighty-four, and from him he removed an enlarged gland weighing 6¼ ounces; his youngest patient was fifty-three years old. The largest tumor shown weighed 14¼ ounces. The speaker noted the fact that a small growth might sometimes cause as much or more obstruction than a large one, and this he attributed to the variable tension of the rectovesical fascia. In 110 cases, three were found to be carcinoma, and in the series since the introduction of the operation there had been eleven deaths, mostly in very old men. He believed this to be a very satisfactory record, since all the patients reported great functional improvement.

Cause of Enlarged Prostate.—Dr. HERRING then made some remarks on this subject. He said that various alleged causes were mentioned, such as adenoma, adenofibroma, sclerosis, hypertrophy, etc., but in his opinion the change was a chronic inflammation due to bacterial action. He exhibited a large number of injection specimens to show the continuity of the ducts of the gland with the urethra.

(To Be Continued.)

Therapeutic Hints.

Trichophytin.—Experiments by Mario Truffi to determine whether or not the toxins produced by the fungus of ringworm might excite a useful reaction if employed in ringworm, after the manner of those of tuberculin in lupus vulgaris, have been entirely unsatisfactory.—*Monatsschrift fur praktische Dermatologie.*

Dysmenorrhœa.—

Iodide of sodium 0.05
Distilled water ..... 10 c.c.
M. Inject ¼ for a dose, into the lumbar region.
—M. SCHWAB.

Calcium Chloride as a Hæmostatic.—

℞ Calcii chloridi (crys.) ..... ʒiv
Syr. opii ..... ʒiii
Aquæ ..... ʒiv
M. Sig. To be taken in 24 hours—renewed until hemorrhage stops. —BARTIGNON.

Diuretic.—

℞ Ext. convallariæ .....
Pulv. convallariæ ..... āā gr. i
For one pill, to be given morning and night.
—MARTIN.

Acute Tonsillitis.—Apply once or twice a day a solution of silver nitrate 60 gr. to 1 ounce—this may abort the disease in one case out of four. —Ingals.

Injurious Effect of Potassium Iodide upon the Eyes.—Galezowsky advises strongly against the use of potassium iodide in syphilis of the eyes. An account of the dilatation of the cerebral blood-vessels it may prove injurious to the retina. In the same manner the state of the nasal and ocular mucous membranes of some people render them peculiarly susceptible to corneal complications developing under the influence of the potassium iodide.

Progressive Muscular Atrophy.—Inject strychnine from $\frac{1}{50}$ gr. up to $\frac{1}{20}$: after two or three weeks omit for a week. —Sir Wm. Gowers.

Avoid complications, avoid exposure to cold and wet, avoid stress, particularly if there be bulbar paralysis. Be careful in feeding to avoid bronchopneumonia from food lodging in the bronchi. —F. W. Mott.

Eye Bruises (Black Eye).—

℞ Acidi acetici dil. ..... ℥v

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 13, 1904:

	Cases.	Deaths.
Measles	95	8
Diphtheria and croup	211	23
Scarlet fever	50	2
Smallpox	...	1
Varicella	9	...
Tuberculosis	328	153
Typhoid fever	86	18
Cerebrospinal meningitis	...	24

Mortality in India.—India is perhaps most commonly known to us as a land of famine and plague and cholera and a population of 300,000,000. The recent blue book issued by England tells some astounding facts about the Indian people. The death rate is given as 17.3 for upper Burma, 44.1 for Punjab, an average of 31.49, or just double the average in England and Wales. And yet, in spite of that, the birth rate for the country was 39. per 1,000, two and a half times that of England and Wales. and rising in one province to the enormous figure of 56.9. It nowhere fell below 23.9.—*Boston Transcript.*

A Red Cross Home.—The Kansas City *Star* describes at length a project of Dr. Joseph Gardner of Bedford, Ind., for establishing a central home of the International Red Cross Society. In order to render this project effective, Dr. Gardner has donated to the Red Cross a tract of 782 acres, four miles south of Bedford, as a "thank offering to humanity." In giving the tract to the Red Cross Dr. Gardner suggested that it would make an admirable location for the American storehouses, invalid homes, hospitals, and nurse school supply depot of the Red Cross in this country. This suggestion has been approved by the Red Cross officers. It is abundantly supplied with pure water, and its perfect drainage, high location, and sufficient transportation facilities make it an ideal place for extensive public institutions. Hospitals and homes for infirm nurses will be established by the Red Cross.

A Training School Yell.—The *Capital* of Topeka, Kan., prints the following as the yell of the class of '04 at the Wichita Training School for Nurses:

Staphylococcus, streptococcus,
Microbes all!
Sterilize and fumigate,
Watch them crawl!
Big germs, little germs,
Short and tall;
Fat germs, lean germs,
We kill them all!
Antisepsis, that's our call,
We're the largest class of all!

When and When Not to Operate on the Mastoid Bone.—H. Gradle gives the following operative indications in acute mastoiditis. The least suspicion of intracranial extension based on persistent one-sided headache or on any cerebral symptoms gives an immediate vital indication. Whenever a perforation threatens, it should be anticipated by operation, and if it had opened spontaneously through a narrow fistula the danger of pus under tension should be obviated by better drainage. Perforation is inevitable whenever the posterior wall of the meatus of the ear begins to sag, whenever the soft tissues behind the ear show inflammatory infiltration (not merely a pale œdema) or when infiltration begins around and beneath the tip of the mastoid. When the characteristic signs of mastoiditis, viz., pain and tenderness, continue to increase after the third day, or even increase rapidly after the second day, immediate operation is the safest course. When the discharge of acute otitis with mastoid symptoms does not diminish at all in the course of about two weeks of appropriate treatment, chronicity must be expected, even though the mastoid signs diminish. Hence, an operation is proper If the mastoid pain and tenderness begin to diminish after two or three days of climax, the operation may be deferred. Those cases in which the mastoid symptoms remain stationary after the first two or three days belong to the debatable class in which it is difficult to say whether to operate or to wait. If mastoiditis follows ostitis, the discharge of which has ceased, the need of operation is greater than when there is still discharge from the middle ear. Streptococcus infection means greater danger and more need of operation than the presence of the pneumococcus or staphylococcus in the pus of the middle ear. We must generally be prepared for operation, however, until recovery has begun. In cases of doubt an unnecessary operation may be safer than any unreasonable delay. In all acute cases the only operation to be considered is the opening of the mastoid. In chronic disease of the middle ear, it is not proper to resort to operation in the absence of any urgent symptoms until a thorough trial has been given to non-operative treatment. If after all conservative methods of treatment have been tried sufficiently long, there remains a discharge free from odor, the danger to the patient is not greater and probably less from the disease than from the radical operation. If the discharge remains fetid, danger from the disease is as great if not greater than from the operation, while the latter offers at least complete exemption from future danger if not the certainty of a cure. Caries of bone likewise may enforce the indications for operation, but not in every instance. A prompt radical operation is the only safe course in all instances in which irritative symptoms indicate active extension of the disease.—*Illinois Medical Journal*

Health Report.—The following cases of smallpox yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service during the week ended July 13, 1904.

THE SUBTLE POWER OF RADIUM.*

By ROBERT ABBE, M.D.,
NEW YORK.
SURGEON TO ST. LUKE'S HOSPITAL.

ASSUMING that few members of even so prominent a group of American surgeons as comprise this association have been able to secure specimens of the strongest radium by which to judge of its value to medical science, it gives me pleasure to put on record such observations as I have been able to make during fifteen months with the best radium made by the laboratory of the Curies in Paris. I was able, by cabling a very early order, to get fifteen centigrams (2¼ grains) of the strength 300,000, which was part of the larger amount used by them in their experiments for calorimetric determinations (now historic).

With this and other strong specimens obtained later, including one of German manufacture, denominated a million activity, I have been able to verify most of the interesting work of the foreign observers, and to add some of my own, which will be of special interest to this audience.

Omitting the historic and almost romantic narrative of research and discovery of radium, we may start at the point where M. Curie delivered to M. Danysz of the Pasteur Laboratory a few grains of the same strength as that which it has been my pleasure to use, for the purpose of animal experimentation. In the early spring of last year the first report was made by him to the French Academy. For the purpose of my paper, I will merely extract a few statements.

If the radium, sealed in its glass tube, be placed in contact with human skin for three hours, more or less, it produces a painful burn, followed by sloughing and slow cicatrization, somewhat like the Röntgen ray burn.

With animals, the guinea-pig being specially susceptible, the hair falls and burns follow on the skin. If suspended some inches above young mice, a week old, they are soon killed, exhibiting these symtoms: after three or four hours, irritation, followed by "dopy" condition, progressive paralysis of their hind legs, convulsions, and death. Examination shows congested and inflamed brain and spinal cord.

When seeds are exposed to radium for a few days before planting, they either do not grow or show feeble power.

When two groups of meal worms are placed in jars, in one of which radium is suspended, many of the radiumized worms die—but those which live on show such retardation, that while those of the control test pass through the cycle of life, becoming beetles, which lay eggs, which grow to worms during the allotted three months, and repeat this cycle three or four generations, the radium worms still remain meal worms, veritable Methuselas, as it has been said.

*Read at the St. Louis meeting of the American Surgical Association.

While these experiments were going on, a sufficient amount was furnished also to M. Danlos in the hospital, and experiments were conducted which showed a strong curative power over lupus and superficial epitheliomas, with even destructive effect when too long exposed.

These results resembled those of Finsen light and Röntgen rays, but were more inexplicable as they seemed to emanate from a spontaneous indestructible, unlimited source, emitted by the radium salt, through its glass tube.

My own experience has been largely in an experimental therapeutic line, in application to some forty cases of types of disease, illustrating mostly its action on superficial morbid growths.

Time permits mention of only a few. First and simplest of all, I would like to record a fact which I have not seen mentioned elsewhere, that the ordinary wart (verruca vulgaris), no matter how long existing, has disappeared in five cases to which I have applied radium by laying it in contact for an hour, from one to four times. In three or four days, a pink zone appears about its base and it begins to flatten, and usually disappears inside of ten days, leaving a smooth skin.

This illustrates the retrograde action in morbid cell growths, which may also be seen in tumors of lupus or malignant type.

I am able to show a photograph of an ulcerating lupus of the temple in an elderly subject, which I had been treating for eight years with the usual result of brief cures, and recurrences. One year since he presented himself after a year's absence with a worse condition than ever—I covered the sore with gutta-percha tissue and held the radium tube against it by bandage for an hour and a half. He went to his country home, and I did not see him for a month. Then he presented himself entirely healed. I am able to show you the photograph, taken before and after.

In one case of a most painful and intractable epithelial ulcer of the ear, spreading during two years, and eating away the upper rim (Fig. 1), I tested the comparative action of Röntgen rays and radium. The ulcer was an inch long by a half inch wide. I covered half by lead plate and exposed the other to radium for a half hour; then at the same seance I exposed the other half to *x*-rays for two minutes.

Repeating this every other day, I found rapid healing under both methods. On both, the hard edges flattened, ulcer filled up with pink granulations—newly cicatrizing skin appeared at the edges. By the sixth time the radium was ahead in its efforts, and islands of new skin appeared half healing the sore. After two applications more, however, the *x*-rays had caught up and gone ahead. The patient being anxious to leave town (this being June of last year), I gave a few more two-minute applications of *x*-rays and sent him home to the country. The ulcer very soon healed completely, with soft cicatrix, and has never shown the slightest tendency to recur. (Fig. 2).

Three months later I took a cast which

contrasts with the other one taken before radium treatment. On the second cast we notice a thick spot (red in the original) one-third inch long, on the lower portion, which the patient says is just like the one above as it first began—but he has one also on the other ear. It would not be possible to find two coincident growths more alike, and they gave me an opportunity to compare radium with

Fig. 1.—Epithelial cancer of the ear treated by radium.

x-ray in different localities. To one, I applied my radium a half hour; to the other, *x*-ray as before (two minutes.) Colored casts shown at the meeting but photographs only shown here.

Three applications of each caused absolute disappearance of both. For three months nothing could be seen on either ear. Then the *x*-rayed spot showed a little thickening, which one applica-

Fig. 2.—Same as fig. 1, showing the results of treatment; the patient remains cured after one year.

tion of two minutes cured for good. The radiumized spot has never come back. One year has elapsed, and his ears are without a blemish. A second case (Fig. 3), of two years' growth, resisting all treatment, was speedily cured by six applications.

Considering larger malignant masses, I am able to show you two casts showing positive result of radium only. Along the scar line of an operation done two years before, by me, for cancer of the breast, there came three small nodules in a line, which grew to represent the size of a man's thumb. I laid the radium tube upon these every other day for an hour; a different place each day. On two occasions a blister formed, but quickly healed.

All three masses were slowly reduced in size until after three months (twenty applications), I took the second cast, showing the growth only about one-quarter the original bulk. A retrograde

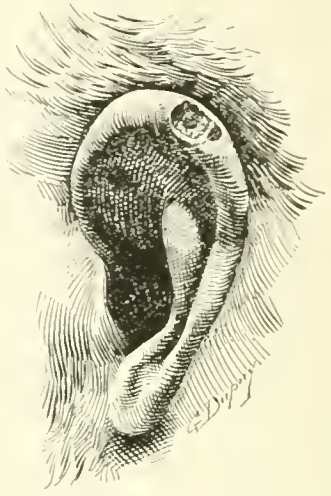

Fig. 3.—Epithelial cancer of the ear, before treatment; a cure was effected by six applications of one hour's duration each, of radium (300,000).

action had everywhere supplanted the progressive growth.

I now desire to record one more marked illustration of the power of radium, and one which gives me greater hope of its utility in surgery than any illustration I have seen.

A lad of seventeen years came to me eight months ago with a soft tumor of the lower jaw-bone bulging within and without. (Fig. 4).

It replaced the substance of the bone, except its lower border, from the middle line toward the left for an inch and a half. In thickness it was one inch, and in vertical measurement the same.

Two incisor teeth and the canine were so loosely

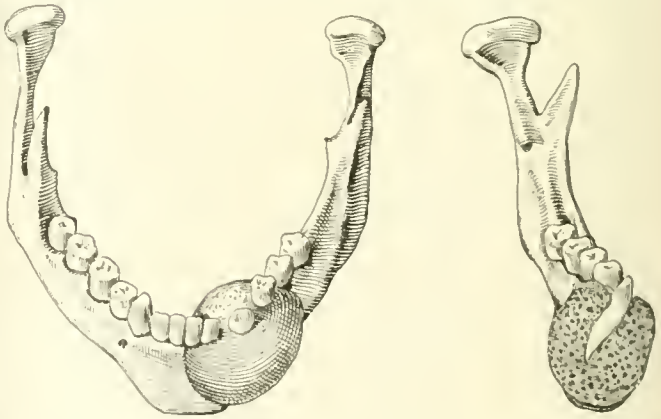

Fig. 4.—Exact representation of a giant-cell sarcoma of the jaw of rapid growth during two months; prior to treatment by radium rays.

imbedded in it that one might have pulled them out by a string. Pressure of one finger under the tongue and one outside gave a soft and almost fluctuating sensation.

On the inner side an ulcerating surface rose half way up on the teeth; and from this a deep piece was cut out for microscopic study. It revealed a giant cell sarcoma. Two submaxillary lymphatics were felt in the neck. From a surgical point of view, it could only be looked upon as a tumor of great malignancy, as it had grown but two

months, and under usual procedure would have required the mutilating operation of excision of at least the half lower jaw.

I decided to give trial for at least two weeks to

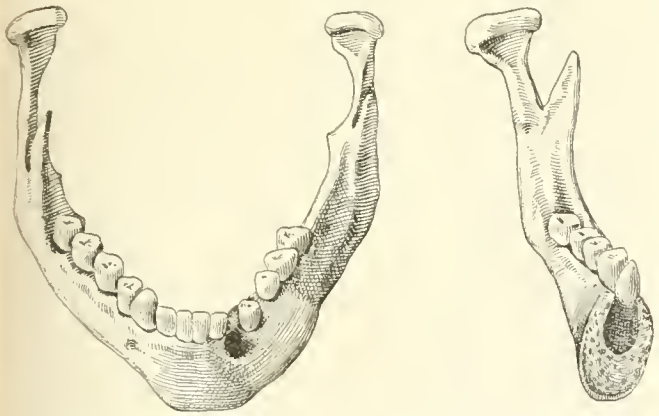

FIG. 5.—Giant-cell sarcoma of the jaw six months after treatment by radium rays was begun.

radium treatment, and continue if anything hopeful followed.

Having taken casts, photographs, and measurement for identification, I attacked the portion under the tongue first, as being most accessible to watch, and as presenting an ulcerated surface, the area of one's little finger nail, on a soft mass growing inward.

I used two grains of French radium (300,000) in its glass tube laid upon the part inside the teeth, with a bit of lead plate to protect the tongue. After four applications of one hour each every alternate day, a marked change was shown. The purple exuberant ulceration grew pink and small and the whole soft internal tumor was shrinking. After the eighth application the entire interior portion had flattened and become hard.

At irregular dates during the next two weeks I made brief applications to this inner aspect.

The effect was so encouraging that I now attacked the outer part. The radium was laid between the gum and lip, but blistered the mucous membrane.

I then determined to plunge it directly into the tumor, although I feared its radiation would be lost in the circulating fluids, as shown by animal experiments in France and Germany, and by myself in the Laboratory of St. Luke's Hospital.

It is usual for a tube of the strongest radium, when sterilized and embedded either in muscle, cellular planes, or peritoneum of an animal, to be encapsulated and apparently inert for from one to three months. I ventured, however, to pierce the tumor by a fine knife placed in front of the teeth and thrust vertically to the lower bony shell. The tumor was uniformly soft, so that the knife penetrated almost by its own weight, and when it was withdrawn blood flowed freely, but was checked when the radium tube was pushed into the knife channel. The tube was half filled by the radium, which occupied nearly an inch in length, and was therefore all buried in the tumor. I left the radium *in situ* three hours. On its removal a piece of gauze, with powdered boric acid rubbed into it, was laid over the spot, and held there for ten minutes.

The treatment was repeated three times weekly for fifteen times. During this period there was a slight but progressive reduction in the bulk of the tumor. Twice I allowed a long interval to elapse because I saw an inflammatory swelling, which at once quieted. The thrust of the knife was usually made at a new point, and it was most interesting to note a gritty feeling of ossification beginning in some places, and less hemorrhage as shrinking progressed. Daily the loose teeth became firmer and stood straighter in their places, which corrobor-

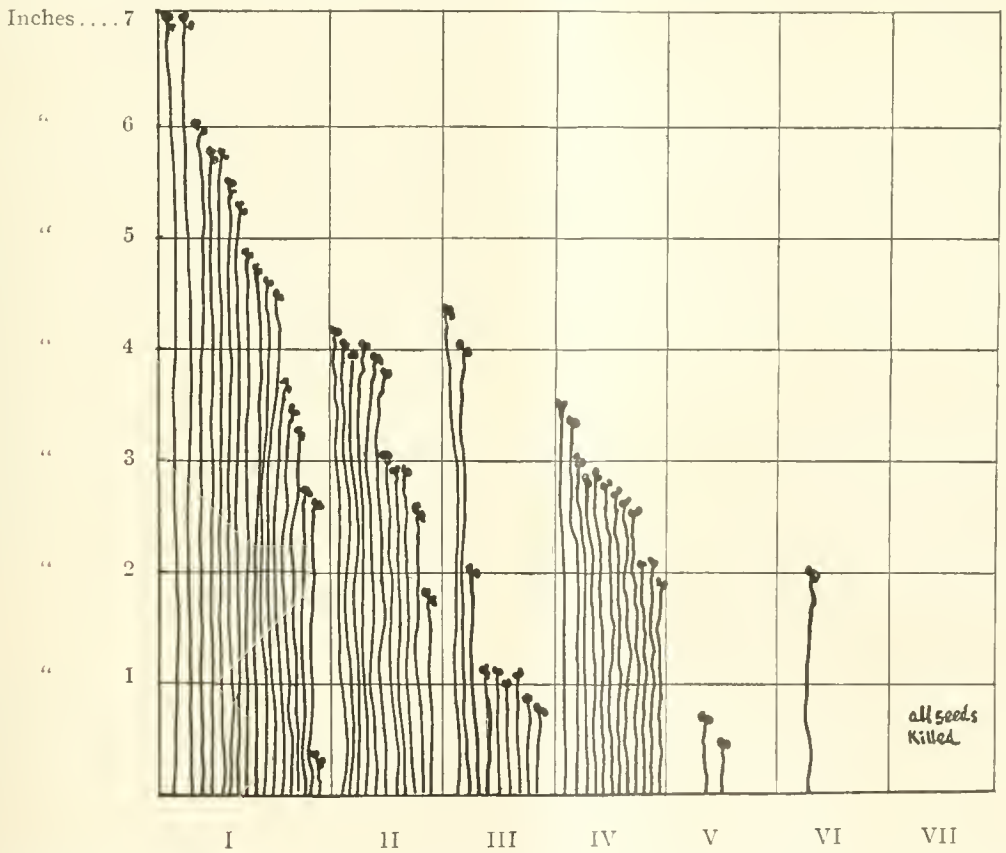

FIG. 6.—Diagrammatic representation of seed growth following exposure to radium rays; twenty seeds in each exposure; I, without exposure, 17 seeds grew; II, exposure for 2 days, 11 grew; III, 3 days, 9 grew; IV, 4 days, 12 grew; V, 5 days, 2 grew; VI, 6 days, 1 grew; VII, 10 days, none grew.

ated my feeling of satisfaction, up to eight weeks of treatment.

Then was noticed a dry black spot near the canine tooth, which spread until a small central piece of the tumor sloughed, leaving a cavity but not affecting the teeth.

Finally a severe grade of inflammation attacked the skin over the tumor and also the half lip, producing a brawny swelling wholly unlike infection but like the inflammation seen in applications of radiant energy elsewhere. This appeared three weeks after the last application of radium, and was so severe that I feared I had done too much and that an external slough would result. A soothing lotion controlled it, however, and after four days it rapidly subsided. During the succeeding four months no treatment has been given, and retrograde shrinkage of all the peripheral remnant of the original growth has followed with progress toward an apparent cure (Fig. 5). The teeth remain firm. The walls have retracted to nearly a natural line and ossific changes have established themselves. A recent examination of a small bit punched out of the center with difficulty, still shows giant cell element, however. This is of great interest and will be spoken of later.

Meanwhile two considerations of the action of radium on growing cells may occupy our attention as they enter into the discussion of the action of this unique force.

The first, is its effect on growing seeds. The second, a microscopic study of its action on malignant cells.

The accompanying illustration (Fig. 6), from photographs of seeds grown for two weeks after being in contact with the tube of radium for varying periods before planting, shows that plain seeds grew seven inches tall, while radiumized seeds were retarded or killed. Rapeseed was used, grown under glass.

To study the immediate effect of radium on cancer under the microscope, I made this experiment.

A mammary cancer required amputation, the breast presented a solid growth, and two secondary superficial flat nodules, each a half inch in diameter. One week before operation I laid the radium tubes on sound skin within the field of operation, for twelve hours, and obtained a lively effect.

On each of six days I chose a different place, once over a secondary growth, and once by direct thrust into the substance of the tumor, where it remained for twenty-four hours. The entire series was then submitted to careful pathological study, after amputation, with these results:

On healthy skin, complete superficial necrosis of the skin took place, with evidence of deeper inflammation shown in leucocyte infiltration into the cellular tissue, and about all the vessels and nerves, with some thrombosis of the small vessels.

Where the superficial cancer area was, there was a marked change. Dissolution and retrograde change in nests of cells near by the radium and less at a distance.

Where the radium was thrust into the tumor, sections were made at right angles to the line of the tube, and a marked sphere of influence was uniformly shown for a quarter of an inch, on all sides. The nests of carcinoma being unchanged outside that limit as far as could be seen, but within it there remained none but degenerated and disappearing cells. What would have been the effect had the pathological change gone on, cannot be said as regards that specimen, because the operation had ended what retrograde changes had been initiated. Microphotographs, casts, and models, of these and other cases, can be studied at the radium exhibit in the government building of the St. Louis Exposition.

To supplement this research, however, I have removed one of the three masses in the patient noted in the early part of this paper, who has had treatment for three months. This mass which had shrunk to one-quarter the former size under radium, showed structure of malignancy still, but with predominance of fiber structure.

What then is my conclusion from the above observations? It is this: Those malignant cells which have escaped destruction and retrograde change, show a striking quiescence; which may mean death of the vital force which makes them malignant. In this connection we cannot fail to be reminded of the seeds which do not grow, and the meal worms which are arrested for an indefinitely long period.

We do not know what constitutes the malignancy of cells. It may not be of germ origin, but merely the erratic and disorderly growth of cells, which have lost their innervation, and grow wildly. A regenerating power may be supplied by the so-styled bombardment by particles of radium atoms carrying each its charge of negative electricity. This must be, as yet, speculative.

The element of heat production is certainly not enough to produce destruction, but an effect such as is shown by Röntgen rays, which seems capable of setting up an inflammation of an entirely unusual type, irritative rather than bacterial, is certainly produced. Whether extreme stimulation is the cause of destruction of some cells; and moderate stimulation the regenerating effect on others to bring them into the line of orderly growth again, will have to be shown by further study. Bactericidal action of radium seems to me to be too feeble and inadequate to account for all we have seen.

It stands proved then, that we have to deal with a very subtle force, unlike that of Finsen light or Röntgen rays, though strongly resembling them in effect; and efficient in some cases in which these fail. The Becquerel rays given off by radium may be rated, as much stronger than Finsen light, as they are weaker than Röntgen rays. It is to be hoped that larger amounts of strong radium may be available for many observers of larger opportunities to aid in further research.

13 West Fiftieth Street.

Heine's Homœopathic Joke.—Ughetti's work, "With Physicians and Clients," contains an anecdote about Heine which is not yet worn threadbare. Returning from a journey to the south of France, Heine met a friend in Lyons, who gave him a large sausage that had been made in Lyons, with the request to deliver it to a mutual acquaintance, a homœopathic physician in Paris. Heine promised to attend to the commission and entrusted the delicacy to the care of his wife. But as the post-chaise was very slow and he soon became ravenously hungry, on the advice of his wife, both tasted of the sausage, which dwindled with every mile. Arriving at Paris, Heine did not dare to send the remainder to the physician, and yet he wished to keep his promise. So he cut off the thinnest possible slice, wrapped it in a sheet of paper, and enclosed it in an envelope, with the following note: "Dear Doctor —From your scientific investigations, we learn that the millionth part of a certain substance brings about the greatest results. I beg, therefore, your kind acceptance of the accompanying millionth part of a Lyons sausage, which our friend gave me to deliver to you. If homœopathy is a truth, then this little piece will have the same effect on you as the whole sausage. Your Heinrich Heine."

CONCERNING SHOCK.*

WITH A CONTRIBUTION TO ITS PATHOLOGY.

By FRANK P. VALE, M.D.,
WASHINGTON, D. C.

In spite of the advances made in surgery in the past half century, since the introduction of anæsthesia and the doctrines of antisepsis, there remains one most dangerous factor in all operations—a condition we call shock. Anæsthesia has robbed surgical intervention of many of its previous terrors, an aseptic technique has practically eliminated the dangers of wound infection—shock, however, remains an unknown quantity, an undeterminable factor in most instances.

From the writings of the surgeons of the first half of the century previous to that just closed, this dreaded factor in modern surgery, most dreaded because now the least determinable, does not seem to have attracted much attention. Nor is this strange when we remember what, as they appear to-day, elementary problems engaged attention. They had not an inkling of the healing of an amputation wound by first intention, almost as many weeks as now days being required in its treatment. Primary and secondary hemorrhage were disasters but imperfectly combated. "The few who survived the bleeding lingered through all the miseries of a nine months' cure, tedious and imperfect, with a conical, ulcerated, and tender stump."[1] The dangers of wound infection were a closed chapter for the next century.

Yet even at this date—early in the eighteenth century—the primary, often fatal, effect of serious trauma, as that produced by firearms, and which we now describe as shock, had been noted. It is in what purports to be the first treatise on gunshot wounds by LeDran in 1737,[2] that we first find a description of this primary effect of an injury. "Such wounds," he writes, "require the surgeon's greatest attention, because they are all complicated, and the bullet, or whatsoever body it is, thrown by gunpowder, acquires such a rapid force that the whole animal machine participates in the shock ('secousses') and agitation which is communicated to the part the moment it is struck. It is scarcely possible that a solid body, driven by gunpowder, should strike any part without communicating at the same time an agitation proportionable to the quantity of matter, to its velocity, and to the resistance of the part. This agitation is technically termed 'commotion,' and we learn from daily experience that it is often communicated to the whole machine, whereby the nervous system (?) is galled and irritated, which puts it in a state of erethism or tonic convulsion, a source of serious accidents. Thus some wounded experience torpor and dulness (*un engourdissement general avec pesanteur*); others have repeated faintings; some have convulsive movements, as hiccup, vomiting, irregular shiverings, or a general rigor; some become yellow, green, or leaden colored, etc."

The symptoms of shock, then, are first described in connection with gunshot wounds, it being conceived that the bullet or ball, in proportion to its velocity and mass, communicated a motion or agitation to the part, which often extended through the whole body, thereby irritating the nervous system. Indeed, nearly one hundred years later, little has been added, and these conceptions are little modified. Thus, in 1826, Travers describes the "Proximate cause of death in these cases as a species of functional concussion, by which the influence of the brain over the organ of circulation is deranged or suspended" —not a great advance over the organic concussion or "commotion" of LeDran.

*Being part of "An Essay on Shock," awarded the Essay Prize (January, 1903) of two hundred and fifty dollars by the Medical Society of the District of Columbia.

To within recent years we find this concussion theory persisting. Fischer,[3] in 1870, writes: "Shock is produced simply by the concussion of the part, independent of pain or loss of blood." Groeningen, also a frequently quoted German authority on this subject, in 1885 ascribes the nerve irritation and exhaustion to the "vibratory" effect of the injury.[4] And in one of our 1901 textbooks[5] shock is described as the result of reflex paralysis of the vasomotor nerves "caused by *traumatic concussion* of a part of the entire body."

Travers is often referred to as having first employed the term shock in its present sense. As early as 1747, however, in an English translation of the treatise of LeDran, above quoted, we find it employed practically as to-day. "The shock with which the patient finds himself, as it were, thunderstruck at the time of the blow, together with the commotion and agitation, may be followed by fatal consequences." (*Le saisissement dont le malade se sent quelquefois frappé à l'instant du coup et la commotion peuvent avoir des suites funestes.*) And Sir Astley Cooper in his lectures[6] mentions "shock" to the nervous system as the most severe manner in which injuries, producing fatal consequences, destroy life—describing a case admitted to Guy's Hospital early in his career, in which death followed a few hours after a crushing injury to the knee, though there was neither a wound nor hemorrhage.

Certainly, however, in Travers' work on irritation,[7] which is really a treatise on surgical pathology—an old dictionary indicating that the doctrine of irritation taught of the immediate and remote effects of injury—we find a more complete consideration of our subject than at any previous time. "Although," he writes, "the fact of death ensuing upon injury of parts not essential to life, even when unattended by hemorrhage, and upon operations not usually esteemed hazardous, has not escaped observation; writers and teachers seem to have contented themselves with the bare statement of it, either from an impression that, being equivalent in effect to death on the spot, or being due to idiosyncrasy, moral or physical, the further consideration of the subject in a practical view was unavailing." Travers' work thus called attention to this condition, and marks an epoch in its history. Thereafter we find a rapidly increasing literature, yet nearly fifty years elapsed before any material addition was made to our knowledge of shock.

In 1834 it was the subject of the graduating thesis of Delcasse. "*La commotion*" he defined as the general or local agitation experienced by certain parts of the body as the result of a fall or a blow. The "*chocs*" were supposed to be transmitted in greatest force through the osseous system. He introduced one important new statement: "It is an arrest of innervation, without which all organs fall into inactivity, their functions suspended."

Dupuytren[38] likened the stupor following wounds to syncope from hemorrhage, the loss in shock being a "hemorrhage," so to speak, of "nervous fluid" or nerve energy. In 1859 Gross[39] somewhat amplified this idea.

Savoy,[8] in 1860, states that death from shock is due to sudden and violent impressions on some portion of the nervous system, acting through it on the heart. This, he writes, is confirmed by the condition found post mortem—the heart full of blood, its cavities distended, and venous system engorged.

In 1870 LeGros Clark,[37] following Ferneux Jordan,[40] described shock as a vital depression—a collapse of energy from a diversion of force—characterized by an influence exerted primarily on the nervous system

and heart, and secondarily on respiration, assimilation, secretions, and senses. Shock resulted from impaired nerve function.

EXPERIMENTAL INVESTIGATIONS.

The first experimental light thrown on the pathology of shock was in 1872. The oft quoted experiments of Goltz are the starting point of our modern conceptions. In his physiological investigations of the heart, in frogs, diastolic arrest was noted following a blow on the abdomen; and though the heart resumed its functions after a pause, it remained pale and transparent, but little blood flowing into it during diastole, and consequently its slow and laborious contractions forced scarcely any into the arteries. On opening the abdomen the vessels were found distended and engorged; if the frog was held in a vertical position scarcely a drop entered the heart, but if held horizontally a small amount of blood trickled in and the circulation was thus feebly maintained.

Here evidently was the explanation of the small weak pulse of low tension, clinically such a prominent feature of shock. The symptomatic resemblance of this condition to hemorrhage was manifestly due to the large amount of blood withdrawn from the general circulation and stagnant in the large abdominal veins. In shock the patient was said to bleed into his own vessels—a so-called "intravascular hemorrhage."

Certainly this was an attractive theory, but as Mansell-Moulin[9] pointed out in 1879, if dilatation of the abdominal vessels was the main factor in the production of shock, the general vasomotor paralysis following section of the cervical cord would result in immediate death. "The extreme loss of blood pressure in shock," he said, "is only a lesser degree of that which takes place normally during the death of an animal."

It was but a short step to the extension of this theory of abdominal vasomotor paralysis to one of general vasomotor paralysis, which to-day is generally accepted. The most recent noteworthy experimental contributions to the pathology of shock have been made by Crile.[10] He also regards general vasomotor paralysis, due to exhaustion of the vasomotor center, as the essential feature of shock. His experiments have dealt in an exhaustive manner with the low blood pressure of shock.

There is abundant evidence of impairment of the vasomotor mechanism in shock, but it has never been demonstrated that there exists a vasomotor paralysis which can be likened to that following section of the spinal cord, which alone approximates the low blood pressure of shock. And some of the experiments of Höber[11] demonstrate that the reduction of blood pressure, following section of the cord, is greatly increased with the shock induced by the intraperitoneal injection of 25 c.c. of a 5 per cent. soda solution—this being added, the excessive reduction of pressure invariably determining a fatal issue.

My investigation of the changes in the specific gravity of the blood and tissues following section of the spinal cord demonstrated that the complete vasomotor paralysis thus produced, drained the tissues of fluid, just as does a hemorrhage. While on the contrary in shock I found the very opposite condition to exist, which leads me to the conclusion that vasomotor paralysis at all comparable to that following cord section—which is essential to the accepted explanation of the low blood pressure of shock—does not exist, and that we must therefore look for other factors in the production of the low blood pressure of shock. In fact it seems to me we have sufficient data to enable us to say that shock is not due to the exhaustion of any one nerve center, or paralysis of any one system, but that the function of every organ, tissue, and cell in the body is depressed as the result of a powerful impression on the nervous system, which dominates all the functions of life.*

Experiments I have performed suggest that an outpouring of lymph into the tissues, in excess of normal, and consequent inspissation of the blood, is one factor which, added to the lower vasomotor tone occurring in shock, aids in the excessive reduction of blood pressure so characteristic of that condition. This loss of fluid by the blood in shock, a state of vital depression but little short of death itself, conforms to the act long well known that after death fluid passes into the tissues from the blood-vessels. This loss of fluid by the blood and corresponding gain by the tissues as death occurred, was sought for and noted in rabbits—as demonstrated by a gain in the specific gravity of the blood and loss in specific gravity of the tissues. In traumatically produced shock (in contradistinction to the shock or collapse of burns and peritoneal irritation or inflammation) I invariably noted this same increase in the specific gravity of the blood and corresponding loss in specific gravity of the tissues. My experiments were suggested by those of Copeman, Sherrington, Lazarus-Barlow, Cobbett, and Roy. In all respects they agree with them, only adding to their investigations a study of the variations in the specific gravity of the blood and tissues in shock produced by a different set of causes, and demonstration that not only is there an inspissation of the blood in burns, as shown by Sherrington, and in peritoneal injuries, as shown by Cobbett and Roy, but also from a variety of other shock-producing influences. I found in all cases of shock, with the exception of those produced by burns and peritoneal inflammation in which there was excited a local outpouring of lymph at the site of injury, an invariable fall in the specific gravity of the tissues, of several degrees, in one case as much as ten degrees; and a corresponding increase in the specific gravity of the blood, except in those cases in which it was reduced by complicating hemorrhage. When there was a local outpouring of lymph, as in burns and peritoneal injuries or inflammation, this local demand drained the other tissues, so that, instead of a fall in the specific gravity of the tissues throughout the body, there was an increase; a marked fall in specific gravity occurring of course in the tissues at the site of injury and local demand. When, however, in my experiments, the burn was not severe, and the local outpouring of lymph not great, the usual fall in specific gravity of the tissues throughout the body occurred. I suggest that, as the regulation of the output of lymph is in all probability a function of the endothelial cells of the capillary walls, the local loss of serum by the blood in burns and peritoneal inflammations is in consequence of the local damage, whereas the general outpouring of lymph into all the tissues in the shock produced by other injuries is to be attributed to the general arrest of cell activity which characterizes shock. Of further evidence of this general arrest of cell activity I shall have occasion to again refer in extenso. The specific gravity of the blood was increased in all cases of shock, including burns and peritoneal injuries, unless reduced by complicating hemorrhage.

Fischer, in 1874,[12] noted the resemblance of a patient in shock to one in the algid stage of cholera. Cobbett[13] again calls attention to this resemblance. In cholera there is a great loss of fluid by the blood; post mortem it is often almost tarry in consistency. Following the experiment of Sherrington and Cope-

*Since this was written Porter & Quimby (*Boston Medical and Surgical Journal*, October 22, 1903), from a different line of experiments, have concluded that exhaustion in the vasoconstrictor neurons cannot be the essential cause of shock.

man [14] on the increase in specific gravity of the blood in shock, produced in dogs by intraperitoneal manipulations, Cobbett and Roy demonstrated that this increase in the specific gravity of the blood was due to a loss of fluid by the blood, which might amount to as much as one-third of its original volume. Cohnheim, in the sixties, had shown that the inspissation of the blood in cholera accounted, in a measure, for the fall in blood pressure and feeble circulation in that disease, by the enormous increase in frictional resistance in the capillaries—resulting in such retardation of the flow that the entire circulation was affected.

In the experiments of Cobbett and Roy dogs were employed, the observations on specific gravity of the blood and tissue being taken frequently and extended in each instance over a period of twelve to eighteen hours. The peritoneal cavity was widely opened, the intestines usually being divided between ligatures. From the very beginning of the experiment the specific gravity of the intestinal wall diminished, and that of the skeletal muscle—representing uninjured tissue—increased; the blood, however, showing no marked change for the first hour or two, but later always an increase in its specific gravity. From this then it appears that fluid was poured out from the blood into the injured peritoneum and subperitoneal tissues, the blood in turn making good its loss from the other tissues of the body, so that no change was noted in its specific gravity for the first hour. At length, however, the supply from the uninjured tissues was exhausted, after which no further rise in the gravity of the skeletal muscles was noted; but the specific gravity of the blood began markedly to increase, and at the end of twelve or eighteen hours in some experiments, was as much as fourteen degrees higher, and the blood was so thickened as to flow with difficulty except from the largest arteries. The failure of the tissues to compensate for the loss of fluid by the blood was also marked by circulatory disturbances; the pulse became more rapid and feeble, the blood pressure falling rapidly two or three hours before death.

To confirm this loss of fluid, specimens of blood were mixed with a solution of oxalate of potash to prevent clotting, and then the volume estimated by whirling in the centrifugal machine. The result agreed with the increase in specific gravity. In clinical support of these experiments Grunbaum is quoted as having noted a rise in the specific gravity of the blood of five to seven degrees, after abdominal operations lasting an hour or more; this increase occurred, however, during the operation and was not delayed as in their laboratory experiments. Demonstrating thus a loss fluid by the blood, Cobbett is led to compare prostration after abdominal operations to the collapse of cholera, dysentery, typhoid fever, and other diseases characterized by a great loss of fluid and consequent inspissation of the blood. The prostration following peritoneal injury he therefore describes under the head of collapse, in contradistinction to the prostration accompanying various other injuries, to which he restricts the term shock.

The experiments of Cobbett and Roy were corroborative of those of Sherrington and Copeman made several years before, adding, moreover, much additional information. The latter investigators in 1893, in a paper on the specific gravity of the blood in various conditions, had noted an increase in its specific gravity in shock. They had desired to observe the effect of tying the splenic vein; an hour and ten minutes after securing the ligature the specific gravity of the blood in the ear was five degrees higher, and in eight hours seven and three-tenths higher. The same increase was found to occur after simply placing the ligature, without tying it; and again when the abdomen was opened, but immediately closed, though the increase was greater if the abdominal contents were disturbed. A forerunner or accompaniment of this increase in the specific gravity of the blood was constant evidence of circulatory disturbances—the ears would become anæmic, heart rapid, respirations rapid and shallow. In another paper, Sherrington demonstrated this same increase in the specific gravity of the blood in shock produced by scalding the animal's legs.[16]

These experiments agreeing in all respects with others of his own on the pathology of œdema and hydræmia, Lazarus-Barlow[16] accepts, in the main, the distinction made by Cobbett between the prostration characterized by the loss of fluid by the blood, as in burns, peritoneal injuries and various intestinal diseases, which has been termed collapse, and the prostration universally termed shock, which he states is characterized by general vasomotor paralysis. In the former condition the loss of fluid by the blood and tissues explained the cholera-like appearance of the patient. In shock the engorgement of the abdominal vessels, Lazarus-Barlow suggests, would have the same effect in abstracting fluid from the tissues. For he had shown[17] that increasing the volume of the blood in the body, by bandaging the extremities, caused an outporing of fluid into the tissues and decreased their specific gravity. After a few hours had reëstablished the normal equilibrium between the blood and tissues, removal of the bandages had the opposite effect on the amount of blood in the body, and increased the specific gravity of the tissues. He suggests the stagnation and accumulation of blood in the abdomen in shock would have the same effect—that of draining the tissues of fluid. But, as I have already pointed out, my study of the specific gravity changes in the blood and tissues has shown that there is not, in shock, a vasomotor paralysis sufficient to produce such an effect.

Quite analogous to the experiments of Goltz are the numerous clinical instances of sudden death from blows on the abdomen, or on the vagus in the neck. Brown-Séquard in 1858[18] pointed out that electrical stimulation of the vagi could produce immediate death, without convulsions or agony, just as after a prick in the region of the apex of the calmus scriptorius, the "noeud vital" of Flourens, or after irritation of the ganglia of the abdominal sympathetic. Death thus produced was characterized by rapid fall of temperature, late appearance of cadaveric rigidity and putrefaction, long duration of the "properties" of the cord, nerves, and muscles, but most distinctively by the arterial hue of the blood in the veins.[19] This latter phenomena was first observed by John Hunter nearly one hundred years before, while bleeding a patient during syncope. What could account for it but an arrest of the activity of nutrition in the various organs and tissues—a diminished production of CO_2 and lessened consumption of oxygen? Scarcely less remarkable was an apnœa, which would naturally give rise to an arterial blood overladened with CO_2, so that the existence of an aerated venous blood would indicate that a most powerful cause was operative in the arrest of metabolic processes. These phenomena were so readily produced by irritation of the cervical cord, that putting some tension on it, by violently bending the neck, sufficed. In this case it might have been suggested that the aerated venous blood was due to irritation of the vasodilator nerves, but Brown-Séquard found that when this arrest of metabolic processes oc-

curred there was also contraction of the blood-vessels; and if one-half the dorsal cord was cut the phenomenon did not occur in parts separated from the brain. In shock experimentally produced he also noted this phenomenon of aerated venous blood.

Laffont, in 1886,[20] in studying the cardiac effects, in dogs, of electrical excitation of the intact vagi, also noted this phenomenon of aerated venous blood. After stimulating the left undivided vagus for ten seconds, there was an arrest of the heart for four minutes, cessation of respirations, minute contraction of capillaries—producing cadaveric pallor of the tissues—and venous blood remained arterial in hue; the only evidence of the persistence of latent life being the contracted pupils.

Roger[21] has made a similar observation. His experiments on shock led him finally to conclusions in accord with those of Brown-Séquard—to the effect that the arrest of metabolic processes is the one constant and essential phenomenon of shock. He produced shock in frogs by crushing the head; there was only a momentary arrest of the heart, its functions soon being resumed. Strychnine was then injected under the skin or into a lymph sack, without convulsions appearing, though they promptly occurred in a control frog. If a lighter blow was struck, the convulsions began as soon as the animal recovered from the temporary stupor produced. Injecting .012 milligrams of strychnine into the abdominal vein of a frog with head crushed, and the same into a control, the latter had violent convulsions at the end of thirty seconds. In the shocked animal there was no response to stimulation until the end of six minutes, and convulsions only at the end of ten—but they were then more marked than in the control, though the condition of both frogs was the same at the end of half an hour. That this absence of the effects of strychnine is not due to circulatory disturbances, feeble heart, and contracted capillaries, Roger shows by maintaining an artificial circulation with a cannula in the aortic bulb; .02 to .03 milligrams were then injected without producing convulsions, .04 milligrams, however, causing a notable increase in the reflexes; having colored the solution, he was able to demonstrate that it had reached the cord.

Contjean,[22] however, contends that in Roger's experiments the strychnine never reached the cord—the crushing blow on the head having opened the carotid, lingual, and occipito-vertebral arteries, which supply blood to the cord. "If one crushes the brain, optic lobes, and even a part of the medulla," he writes "without injury to the occipito-vertebral vessels, and then injects one-quarter of a milligram of strychnine into the abdominal vein, convulsions occur as in the normal animal. And even in a frog with crushed head and consequently 'opened' vessels, if .02 milligrams is injected through a cannula into the abdominal aorta, convulsions occur if the two aortic arches, above the axillaries, are first tied." Nor was he able to confirm Roger's statement that if the frog was only stunned, by a lighter blow on the head, the strychnine effects were postponed, attributing such a result to the weakened circulation alone. On the contrary produce convulsions by the injection of whatsoever dose of strychnine one desires, if the head is crushed they cease immediately; from which he argues that the absence of "strychnisme" in shock is due to an inhibitory effect of the injury on the spinal centers.

I endeavored to ascertain the truth in these conflicting statements, which I have often seen quoted but never further elucidated. I used varying doses of strychnine, from those almost immediately fatal to those showing only slightly exaggerated reflexes at the end of several hours. Contjean's statement that strychnine convulsions always disappear on the production of shock I demonstrated to be true, not only in frogs but in rabbits; in fact, *a priori* it should have been expected, for this inhibitory influence of various injuries is in accord with abundant clinical and experimental experience. My experiments fully corroborate the statement of Roger that in frogs, during shock, the injection of strychnine does not produce its usual effects, and that in lesser degrees of shock it is only as the frog recovers that these effects appear. I noted also the same delay in the appearance of strychnine convulsions, or their entire absence during shock in rabbits. In rabbits one thing that especially attracted attention was that death often occurred immediately or soon after a dose of strychnine, during shock, which, except for the existence of shock, would not have proved fatal. In frogs, in place of a crushing injury of the head, which would "open" the vessels supplying the cord and thus prevent the effects of strychnine, as claimed to occur by Contjean, I inserted into the mouth a small pair of artery forceps and crushed the forebrain without laceration of surrounding parts, leaving the forceps *in situ*. Roger also produced shock by discharging a Leyden jar through the lumbar cord, and obtained the same results as by crushing the head.

I have also corroborated the statement of Roger[23] that the reflex excitability of the cord, after a small dose of strychnine, is greater in a shocked frog than in a control; and that likewise after a large enough dose to exhaust the spinal centers the excitability of the exposed cord to electric stimilation is much greater in the shocked frog; from which he argues that the absence, or the delay in the appearance, of the characteristic effects of strychnine in shock cannot be attributed simply to an inhibitory or paralyzing effect of the injury on the nerve centers.

Clinical experience supports this experimental evidence as to the relative insusceptibility to strychnine in shock; Mayo Robson[24] and other English surgeons recommend that as much as three-fourths of a grain be given during an operation if necessary. That the effects of the drug appear as the shock is recovered from is shown by the untoward, at times fatal, results of this practice.[25] Other drugs are equally without their accustomed effects in shock; Dupuytren said that if he could but see the effects of opium or alcohol he was assured his patient would recover.

I subsequently learned of the experiments of Van Engelen,[26] which are further confirmatory of those of Roger. Shock was produced both by "percussions" on the head, and by the discharge of a Holtz machine. He demonstrated also that the rate of absorption is much retarded in shock. Normally a solution of ferrocyanide of potash injected under the skin showed itself by a characteristic blue reaction with perchloride of iron, in the lymph sacks of the tongue, in four or five minutes, and in the peritoneal cavity in fifteen minutes; whereas in shock it did not appear in the mouth for fifteen or twenty minutes, nor in the peritoneal cavity for twenty to forty-five minutes. But delayed absorption cannot explain the delayed or absent strychnine convulsions, in view of the experiment of Roger, in which a colored solution demonstrated the presence of the drug in the tissues of the cord.

With these experiments in mind and those of Brown-Séquard and Laffont, in which the most characteristic effect was the arterial hue of the venous blood, one is forced to accept the conclusion of the former, that in shock there is an arrest or inhibition of the processes of "exchange," *i.e.* an arrest of metabolic processes—a general arrest of cell activity.

Contjean states, that though this appearance of the blood has been frequently noted by numerous clinicians, and many physiologists, in his experiments—shock being produced in guinea-pigs by crushing the head—it was by no means constant. In my experiments on rabbits this phenomenon of aerated venous blood was only noted after twenty-four to forty-eight hours in prolonged shock, as that produced by injuries to the spinal cord; also in shock produced by section of the cervical cord, and promptly followed by death, the venous blood from the right side of the heart being identical in color with the aerated arterial blood from its left side. Generally the blood became at first darker than normal in shock, and later, if the venous blood had assumed an arterial hue, additional injury again rendered it somewhat darker—which would be naturally expected from the slowing of the respirations and circulation. I have in mind an experiment of Brown-Séquard,[27] on a guillotined criminal, which may be interpreted in support of my assumption, that in spite of the arrest of metabolic processes, waste products may remain in the tissues capable of reducing the oxyhæmoglobin of the blood. Eighteen hours after the death of a criminal, defibrinated, red, arterial blood was injected into the arteries of the hand, and returned by the veins dark venous in color; several times the blood was reinjected, after aeration, with the same result.

In support of his contention that the phenomena of shock are not due to fatigue, Roger states that the contraction of the gastrocnemeus of a frog, in response to a given electrical excitation, is more energetic in shock; and further, relates the effect of faradizing the central end of the left vagus, both vagi being divided in the neck—the venous blood became arterial in hue on the left side but not on the right, faradization of the central end of the right vagus being without effect. Modification of the rhythm of the respiratory movements is an active phenomenon, but repeated several times its effects are less marked, the centers are less excitable. In the same manner, he writes, the bulbar centers had lost their excitability after stimulation of the left vagus, and were incapable of reacting to stimulation on the right side: the phenomenon was consecutive to an excitation and not due to fatigue, otherwise each new stimulation would produce it.

Though modification of the respiratory rhythm through stimulation of the vagus, is an active phenomenon, the subsequent loss of excitability can only be attributed to fatigue of the centers. And so in shock, though the arrest of cell activity may be primarily an active process, in the nature of an inhibition, the nerve centers are overwhelmed and exhausted by a species of overstimulation as the final result. Foster[28] says, with regard to the nature of shock, that in part at least it can be explained by regarding the lesion as a very powerful stimulus, which partly by way of inhibition, but still more by way of exhaustion, depresses or suspends, for the time, normal functions.

In support of the theory of exhaustion of the nerve centers in shock, is the resemblance of the persistent and often increasing debility which follows various injuries—and described by Jordan in 1863 as chronic shock—to neurasthenia or so-called nerve exhaustion. In this connection a histological study of the central nervous system in shock for comparison with the changes in the nerve cells due to fatigue, as described by Hodge[29] and others, would be most interesting.

That mental impressions can produce profound changes in the organism we have abundant proof. One might mention the frequently quoted death of an infant, on being put to the breast of its angry mother; and the authentic cases of the hair turning gray, over night, from mental shock—such an instance being recorded in a recent number of the *British Medical Journal*.[30] There is every reason to suppose that the pathological changes we have described characterize equally the shock produced by psychical influences, which is typified in the attack of syncope. Hill[31] concludes that syncope is due to a sudden and temporary paralysis of the vasomotor center. The observation of John Hunter, over a hundred years ago, on the arterial hue of venous blood in syncope, indicates there is the same general arrest of cell activity as in shock, the feeble heart and paralysis of the vasomotor mechanism being here also only a part of the effect of the impression on the nervous system.

EXPLANATION OF SYMPTOMS

Shock results from an overwhelming impression on the nervous system, either physical or mental, arresting more or less completely the functions of every cell in the body. There results an outpouring of lymph into the tissues in excess of normal and consequent inspissation of the blood—as shown by an increase in its specific gravity—which is one important factor, added to an impaired vasomotor tone, in the production of a greatly reduced blood-pressure. That the enfeebled action of the heart is largely secondary to the lowered blood-pressure is shown by the experiments of Goltz, Cobbett, and Roy; and clinically by the immediate effect in restoring the force of its contractions, from a temporary rise in blood-pressure produced by an intravenous injection of salt solution.

The experiments of Goltz would appear to explain also the cases of sudden death from blows on the abdomen, many examples of which are so be found in medical literature. In warm-blooded animals only temporary arrest of the heart can be produced by irritation of the peripheral end of the vagus; yet clinically it would seem that permanent arrest can be brought about reflexly through the cardio-inhibitory center. The phenomenon of aerated venous blood—resulting from the general paralysis of cell activity and arrest of metabolic processes—witnessed by Brown-Séquard, Laffont, and Roger, after excitation of the vagus, would indicate a systemic effect in shock from this class of injuries as well.

The wan, pinched features are due to the empty peripheral vessels and feeble circulation; undoubtedly, however, most marked where there has been an excessive fluid loss by both the blood and tissues, as in peritoneal injuries.

The cyanotic lips and livid skin are transient, and I believe correspond to the period during which the venous blood in rabbits was observed to be yet darker than normal. A statement made by Norris[32] must be here quoted. He observed under the microscope that where there was spasmodic contraction of the smaller arteries, a reversal of the blood current into the capillaries took place, which continued until they were full, in which condition they remained until relaxation of the artery again permitted blood to be propelled through it.

The lessened secretions, partial and often complete anuria, is due to the lowered blood-pressure. The feeble circulation and lessened activity of all the organs and general arrest of metabolic processes explain the fall in body temperature; if there is a definite thermogenetic center it undoubtedly is also influenced in the general depression of all activities. Höber attributes the fall in temperature to the engorgement of the abdominal vessels and increased dissipation of heat through the abdominal walls.

The shallow, slow respirations recorded in the protocols of Höber and others, and noted by my-

self, is in accord with the phenomenon of aerated venous blood.

Impaired consciousness is due to the overwhelming nature of the impression on the nerve centers, the feeble circulation augmenting and prolonging this effect. Brown-Séquard called attention to the inhibitory effect on consciousness of an insignificant prick in the region of the "bec du calmus;" it was not due to contraction of the cerebral vessels, as it occurred after both sympathetics were cut. In an effort to produce sudden death by a prick of the "noeud vital" I noted this loss of consciousness, the explanation of which at the time was not apparent.

Diagnosis.—The prostration of shock is so characteristic as to cause but little difficulty in its recognition. Late appearance of its symptoms creates a strong suspicion of an overwhelming bacteriological infection. Fat embolism, which otherwise at times might enter into the differential diagnosis, rarely occurs before the end of thirty-six hours, and usually not for three or four days. Sudden arrest of the functions of the kidneys, already crippled by pathological changes, is excluded by previous urinary analyses; generally also sufficient urine can be removed by the catheter for diagnostic purposes.

Collapse due to hemorrhage is practically the one condition to be excluded. Fifty years ago Vierordt[33] showed that after a severe venesection the red blood cells might drop as low as 40 per cent. of the number in the blood first drawn. This fact we apply daily in the diagnosis of internal hemorrhage. As long ago as 1839 John Davy[34] recorded a fall in the specific gravity of the blood in animals "blooded" to death. I do not know that the estimation of the specific gravity of the tissues will ever be of any practical value, yet the variations I have observed experimentally, in hemorrhage and shock, would suggest that we have here a differential sign of considerable importance. In experimental shock an increase in the specific gravity of the blood and decrease in that of muscle was constantly noted. Any hemorrhage more than offset the rise in specific gravity of the blood, due to shock; the muscle, however, continued to show the fall in specific gravity characteristic of shock, unless the hemorrhage was considerable, when there was an increase—due to the fluid abstracted to supply the loss by the blood. My experiments indicated that in hemorrhage, muscle tissue was not drawn on first to supply the fluid lost by the blood—but probably first the peritoneal and other large serous sacks.

In estimating the specific gravity of the blood I can see no advantage in the modification of Roy's method[35] proposed by Hammerschlag[36]; but the latter is preferable for muscle, as only one specimen is required in the demonstration of the specific gravity.

Note.—Since this paper was written I have had a few opportunities to corroborate clinically the experimental findings above recorded, as to the alterations in the specific gravity of the blood in shock.

Case I.—Mrs. D. Operation lasting one and a half hours for closure of a fistula due to a piece of gauze left at a previous laparotomy. Before operation; blood-pressure 140; specific gravity of the blood 1053. End of operation: blood pressure 135; specific gravity of blood 1058. 4 P.M., four hours later, found my patient suffering from mild shock: skin cold and pale; vomiting small quantities of brownish fluid containing red blood cells; temperature subnormal; blood pressure 130; specific gravity of the blood 1063. 6 P.M., patient has had thirty minims of tr. digitalis and one-fifteenth grain of strychnine hypodermically, and a quart of hot salt solution per rectum: blood-pressure 140; specific gravity of the blood 1055. 11 P.M., blood-pressure remains 140, but the effects of the salt solution having passed off the specific gravity of the blood has risen again to 1058, dropping to 1053 the next day.

Case II.—Mr. E. was thrown from his bicycle, while riding rapidly, by colliding with a carriage, the pole striking him violently in the abdomen. Twenty hours after the accident there was evidence of the peritoneal injury in the distension and tenderness of the abdomen; specific gravity of the blood 1063. Forty-eight hours later, these symptoms having subsided: specific gravity of the blood 1058.

Case III.—Mr. McM. Brought to my office suffering from mild shock produced by a fall from a rapidly moving electric car. Specific gravity of the blood 1066. Twenty-four hours later 1064.

Case IV.—Mr. D., member of the district Fire Department, fell twenty feet through the pole shute of the engine house, fracturing his clavicle; was picked up "bathed in a cold sweat." I saw him within half an hour; he had partly recovered from the first effects of the fall. Specific gravity of the blood 1063, which later was found normally to be 1058.

Mercuric Cyanide as a surgical disinfectant has the advantages over corrosive sublimate of not forming precipitates in the presence of albumins and of rapidity of action.—Charles Harrington.

THE CLIMATE OF TIDEWATER VIRGINIA.

By W. A. PLECKER, M.D.,
HAMPTON, VA.

Upon the climate in which he resides, more than upon any other one thing, depends man's healthfulness, comfort, and well-being. Even his mental and moral make-up are influenced by climatic surroundings. The range of climatic variation in which he may live in comfort and pleasure, without an actual struggle for existence, is remarkably small. In the frozen north his energies are consumed in the effort to keep warm. If too far south, the enervating effects of heat render him sluggish and indolent.

If the atmosphere is too dry, evaporation from the skin and lungs is increased. The blood is less diluted and operates as a stimulant to the nervous system. Excitement and sleeplessness follow. This condition is increased if atmospheric pressure is decreased by the high altitude of a mountain climate. If there is an excess of moisture, particularly if combined with the increased air pressure of the low altitude, nervous depression with quiet sleep, decreased elimination of carbon dioxide, and slower circulation of the blood are induced.

If the prevailing winds are from the wrong direction and their velocity is great, the burden of life is greatly increased. There is but a limited area of the earth's surface in which the elements of latitude, range of temperature, proximity to the ocean, and prevailing winds, together with an agreeable amount of moisture and a large proportion of clear days, are found happily blended into one harmonious whole. In the western hemisphere no one spot so nearly meets all the requirements of a perfect coast climate, as eastern or tidewater Virginia, centering around that finest and most beautiful of our American harbors, Hampton Roads.

At this time when the eyes of the world are turned upon this section through the efforts in behalf of the proposed Jamestown Tercentennial Exposition in 1907, it is but fitting that we present a brief analysis of the natural conditions which make the climate an ideal one for residence. Its latitude, 37, is the natural average for the country, 47 reaching nearly to the northernmost point of New England, and 27 to the southern end of the Florida peninsula. This latitude is not far south of the center of population for the country, which is kept from receding southward more rapidly by the large cities, which by the force of their attractive power hold it near the line of Washington. The geologic study of this section shows strata of loams, sands, gravels, clays, and marls. Bed-rock was struck at a depth of 1170 feet in a well bored six miles northwest of Old Point, on the Chesapeake shore. This bed of crystalline rock has its outcropping in the neighborhood of Richmond and slopes to the sea. Excellent artesian water may be obtained, especially a few miles inland, by boring to varying depth. A well on Jamestown island, the site of the first English settlement in America, yields an abundant supply of fine water at a depth of 248 feet.

The alluvial soil is extremely productive, two crops of garden truck and other products being raised each season for local use and shipment. In geologic formation, this district is specially favored. Four large rivers, which are really tidal estuaries, free from overflow, traverse it from the northwest to the southeast, dividing the territory into a succession of long ridges with natural drainage in each direction. It is to this fortunate natural formation that this section is indebted largely for its climatic and other advantages. The entire area is thus divided into a series of peninsulas with salt water on three sides of each. The prevailing winds being from the water, moderate the temperature both in winter and summer.

These prevailing winds are abundantly laden with ozone, of which ocean breezes always contain a superabundance. The natural growth of pine adds still further to this ozone supply, as the wind blows across the peninsulas. Besides opening up the country to navigation, these streams, together with Chesapeake bay and the ocean, furnish a never-failing supply of the choicest oysters and fish, far into the interior. This supply of cheap and wholesome food adds largely to the health and comfort of the inhabitants.

The physician who is considering the question of change of climate for his patient desires information as to the range and average of temperature, humidity, sunshine, prevailing winds, prevalence of zymotic diseases and past experience in cases of a like nature. This we shall endeavor to give, comparing the climate of Hampton Roads with that of several centers of population and resorts to the north.

The data are compiled from the U. S. Weather Reports, and are the average for a period of thirteen years. The records for the region bordering on Hampton Roads are selected as being representative of the whole, and because this is the center to which all visitors come. It is the harbor in which Christopher Newport and Capt. John Smith in 1607, with their band of English settlers, cast anchor after their long voyage across the Atlantic.

To them the placid water of this the finest of our Atlantic harbors was a haven of rest, and the first landing place after entering the capes was surely a point of comfort. In this harbor, in which the navies of the world may, and probably in 1907 will, float, have transpired many events of national history. It was here that naval warfare was revolutionized, when, on March 9, 1862, the ironclad *Virginia* met in battle the first turreted *Monitor*.

At the entrance to Hampton Roads, is one of America's famous resorts, Old Point Comfort, with Fort Monroe, which effectually guards the approach to the nation's capital, and other important cities. Adjacent to Old Point is the town of Hampton, the oldest continuous English settlement in America, the site of the National Soldiers' Home and the Hampton Normal and Agricultural Institute. A few miles further up the shore is Newport News with its great shipbuilding plant. On the opposite side of Hampton Roads are the cities of Norfolk and Portsmouth, fast becoming what location and climate have destined them to be, a great center of commercial enterprise.

Temperature: Winter.—Freezing weather rarely begins before the latter part of December, occurring in spells, lasting usually for two or three days. Entire winters frequently pass with only several of these spells, during which the thermometer falls below the freezing point for a short while. The average winter temperature is 41.9, nearly 10 above freezing. That of Atlantic City, which ranks high as an all-the-year resort, being 33.4, less than 1½ above freezing. New York is 31.4; Boston, 28; Rochester, N. Y., 25.7; Burlington, Vt., 21.1; Toronto, Canada, 19.7.

Summer.—The average during this season is naturally rather higher, though in neither case is the range of temperature as great as farther north. Hampton Roads, 77.4; Atlantic City, 70.4; New York, 71.5; Boston, 69.1.

Spring.—The average for the spring months is 57.1, which is about ten degrees above that of Atlantic City and New York, while the averages of the other places named still hover around the freezing point. It is during this period that we have simply

perfection in climate, with the beauties of budding vegetation weeks ahead of the less favored northern homes.

Autumn.—We again, during this period, have a repetition of the spring season, some even thinking it more delightful. The average temperature is 60.4, while at Atlantic City it is 56; New York, 54; Boston, 51. During this period,as in the spring, all the pleasures of an out-door life may be indulged in to their full.

The Annual Range of Temperature is 96.5; Atlantic City and New York, 106; Boston, 114.5; Rochester, 110; Burlington, 121.8.

Humidity.—After temperature the most important element in the consideration of climate is the degree of humidity. In this respect, too, this section is specially fortunate. While it does not rank in the class with the extremely dry climate of New Mexico and Arizona, yet it stands ahead of all the Atlantic resorts in point of dryness of the atmosphere. For the spring months the mean relative humidity for Hampton Roads is 67.8; summer, 71.8; autumn, 74.8; winter, 72.6; for the year, 71.8. Atlantic City for the year is 79.4, a difference of 8½ points in favor of the former. The average for New York is 69.7; Block Island, 84.5; Nantucket, 80.5. We are even ahead of Jacksonville with its average of 72, and Charleston with 73.8. San Diego, Cal., has the advantage of only 2.3 per cent., the humidity of that place being 69.5.

Sunshine.—Of almost greater importance to the visitor than even temperature or humidity, is the question of how much of the time can be spent out of doors. The Weather Bureau sums this knowledge up by giving the number of fair and clear days for each point. Again Hampton Roads is ahead with 258.8 of such days during the year; Atlantic City, 255; New York, 252; Boston, 237.6; Rochester, 204.8; Burlington, 216.7; Toronto, 181. The amount of snowfall is usually small, and winters may pass with scarcely a time during which the ground is covered for twenty-four hours. Exceptions, however, occur, as during the remarkable winter of 1903 and 1904, when visitors and the young people of our town enjoyed the novelty of skating on Hampton River.

Wind.—The range of temperature may be satisfactory, the degree of humidity just right, and the number of clear days abundant, yet if the wind continues to blow cold and strong, the pleasures of outdoor life are destroyed.

Nature here has favored tidewater Virginia again. Cyclones and tornadoes are unknown, and even during severe windstorms the velocity is less than at points both to the north and south. During the spring and summer the prevailing wind is from the southwest, autumn from the northeast, and in the winter from the north. During much of the time the winter wind is from the water, which greatly modifies the weather.

It is the low velocity, however, which deprives the wind of unpleasant effects. For Hampton Roads it is 7.7 miles per hour; Atlantic City, 9.9; New York, 9.2; Boston, 9.1; Rochester, 9.6; Toronto, 10.

For the student of climatology this summary of the weather condition of tidewater Virginia, is alone sufficient data upon which to base the conclusion that here may be found, happily blended, the climate sought for by sufferers with many forms of disease.

To these climatic advantages may be added the almost entire freedom from malaria and other zymotic diseases, except in a few isolated spots with local causes at work. The cases of typhoid fever which occur are usually of a mild type with a death rate of about 8 per cent. These are generally due to individual carelessness in using water from shallow wells with insanitary surroundings.

What home-seekers, health-seekers, and pleasure-seekers desire to know in connection with the place under consideration, is its comparative immunity from disease and the class of patients that may expect benefit from a sojourn in it. Here vital statistics may be somewhat misleading on account of the insanitary mode of life of the negro population and their greater rate of sickness and death.

As an illustration, while the entire death rate during the year 1903 in Hampton and Elizabeth City County was 16.29 per 1,000, the white rate was 10.5, the colored 22.02.

The same condition prevails in Norfolk, Newport News, and elsewhere. Of the 269 deaths in Elizabeth City County during 1903, 56 were of individuals from sixty-five to one hundred and four years of age.

Persons who visit this section derive all the benefits which may be received from a stay at the seashore anywhere. In addition to this, with the beneficial effect of the relatively dry atmosphere, pleasant sunshiny weather, freedom from severe winds, and an abundance of wholesome sea and garden products at their source of supply, individuals find their appetite increased, digestion improved, and an increased amount of sleep induced.

Tissue changes are accelerated, increased functional activity is induced, and convalescents and chronic invalids soon take on new life and improvement.

Patients with a *tuberculous* and *scrofulous* tendency are benefited by a stay in this climate. This is particularly the case with young children.

Cases of *chronic rheumatism* from the interior do well. The tendency to constipation which sea-air induces should be guarded against by a mild remedy In *heart affections*, especially accompanied by dilatation and an atheromatous condition. high altitude should be avoided. Such patients find this climate specially advantageous. *Asthmatic*, *anæmic*, and *neurasthenic patients* and those suffering with amenorrhœa and any form of sluggish organic functioning, on removal to this locality will, through the stimulating effect of the air, together with an outdoor life, find prompt improvement. The climate is well suited for *Bright's disease and diabetes mellitus*. There is probably no place better adapted to the needs of the feeble aged than this, as is evidenced by the condition of the old men at the Soldiers' Home in Hampton.

Tuberculosis is comparatively rare amongst the white population. The majority of such patients during the early stage and before hæmoptysis, do better in a high, dry climate. Late cases are benefited here.

Dr. Nash says that "persons coming to Norfolk from the New England States with pulmonary disease almost invariably improve."

Major Johnson says "cases of phthisis pulmonalis as a general rule, seem to do very well. Incipient cases do not do as well as those farther advanced."

A patient now under observation, with high temperature, digestive derangement and the involvment of the upper half of one lung, speedily entered the road to recovery, upon being placed during the rigorous winter of 1903 and 1904 in a room with windows and door wide open, and a strong breeze passing over the bed.

Sea-bathing.—It is not the purpose of this paper to dwell upon the advantages of sea-bathing except incidentally to the subject as a whole. As a rule, those who are benefited by the climate, receive additional aid, as well as pleasure,by a daily plunge in the surf, followed by a vigorous rub Persons with heart disease, or internal hemorrhage

should avoid sea-bathing entirely. Convalescents, thin and anæmic persons, should do so under a physician's direction, avoiding a too prolonged stay in the water. Warm baths of sea-water may be beneficial when cold are not.

Desiring to obtain the experience and opinions of other members of the profession, the following circular letter was mailed to a number of the members of the Seaboard Medical Association:

"Dear Doctor: The proposed Jamestown Exposition has caused the eyes of the country at this time to be turned toward this section. It is a fact, which is doubtless known to you, that people residing in the up-country have the idea, generally, that the inhabitants of tidewater Virginia, are continually shaking with malarial chills, and that this is anything but a healthful locality in which to live or visit.

"Desiring to obtain information for use in the preparation of a paper on the climate of tidewater Virginia, I will esteem it a favor if you will answer, by number, upon a postal card or otherwise, the following questions: (1) To what extent and in what form does malaria prevail in your practice? (2) How does its prevalence compare with that of former years? (3) Have you found the Anopheles mosquito to be the responsible cause for such cases as you have seen? (4) Does typhoid fever prevail to any extent? (5) What is the usual source of water supply with such patients? (6) Do any preventable or other diseases prevail greatly? (7) General remarks as to the healthfulness of your locality and tidewater Virginia as a whole. (8) Have you observed special advantages of the climate upon any class of patients from away?"

The replies received are remarkably uniform, and show a general freedom from zymotic diseases, with a steady improvement in the sanitary condition of the towns, reaching to the country districts. In Norfolk, Portsmouth, Hampton, and Newport News, since the introduction of paved streets and sewers, with the general abandonment of wells and cisterns, malaria has almost entirely disappeared except for the imported cases, and typhoid fever has become much less frequent. Dr. Herbert M. Nash alone, during the past fifteen years, has signed one hundred death certificates of persons between eighty and ninety years of age.

Dr. Chas. R. Grandy says: "In Norfolk proper, which is well paved and sewered, there are no anopheles, though there are at times considerable numbers of the genus culex. Our town water supply is filtered and is as good as any in the State. I have never heard of a case of typhoid fever being traced directly to it. I certainly consider this section, as a whole, a healthful one."

Dr. Herbert Old says: "The type of all diseases is the mildest I have ever seen, and I don't believe that there are more than forty days in the year in which the youngest infant can't be out of doors." I have known of asthmatic cases benefited by remaining at Virginia Beach, and young infants take on lost flesh there readily."

Dr. R. L. Payne says: "The healthfulness of Norfolk is remarkable and the death rate (white population) very small."

Dr. Southgate Leigh says: "I look upon this section as a remarkably healthy one. People from the north and west do well here. The climate is mild, winter and summer. I lived in New York City for some time, and comparing the two climates I believe that we have it here cooler in summer and warmer in winter."

Dr. R. L. Murran of Portsmouth says: "I conider tidewater Virginia, as a whole, one of the most healthful localities in the United Sates, as our death rate substantiates." "8. Beneficial to all kinds except lung trouble."

Dr. Edw. E. Field says: "7. A very healthful locality. "8. Yes, upon those who are run down and upon children with enterocolitis but not on consumption."

Dr. Robert Sturges of Tanner's Creek says: "7. Better could not be asked." "8. All cases demanding mild temperature could certainly be benefited."

For the Yorktown peninsula, between the James and York rivers, the reply of Major J. A. Johnson, surgeon for the National Soldiers' Home with several thousand inmates, is so concise that his answers will be introduced entire, as embodying the observation of the present writer, and the experience of other physicians. "(1) I have never seen a case of true malaria in the Home that was not imported. The few cases that I have seen were in men who had been on furlough in Baltimore. Cases were usually of the tertian type. (2) Have not seen a case of malaria in five years. (3) Cannot say [as to anopheles]. (4) No [as to prevalence of typhoid]. (5) Newport News water supply. (6) No [as to prevalence of preventable disease]. (7) Universally healthful, enjoying immunity from epidemic and contagious diseases. (8) Cases of phthisis pulmonalis as a general rule seem to do very well. Incipient cases do not do as well as those farther advanced."

The Newport News Water Company derives its supply from natural springs some miles up the peninsula, and supplies Newport News, Hampton, Phœbus, Old Point, National Soldiers' Home, and Hampton Normal and Agricultural Institute, with the thickly populated territory intervening. Statistics on this point, gathered during 1903 by the writer as County Health Officer, showed only one case of typhoid fever in which the use of hydrant water alone was reported.

The following charts compiled from the U. S. Weather Reports will be found useful by those desiring comparative data:

		Average mean temperature.	Range of temperature	Mean relative humidity.	Average No. fair and clear days.	Prevailing direction of wind.	Average velocity of wind in miles.
Hampton Roads	Spring	57.1	82.0	67.8	64.1	S.W.	8.8
	Summer	77.4	49.5	71.8	68.0	S.W.	6.8
	Autumn	60.4	76.0	74.8	65.3	N.E.	7.2
	Winter	41.9	75.0	72.6	61.4	N.	7.9
	Year	59.2	96.5	71.8	258.8	S.W.	7.7
New York	Spring	47.5	91.0	65.8	63.7	N.W.	9.8
	Summer	71.5	52.0	70.1	67.8	S.W.	7.6
	Autumn	54.3	93.2	70.7	63.8	N.W.	9.3
	Winter	31.4	73.0	72.3	56.7	W.	10.2
	Year	51.2	106.2	69.7	252.0	N.W.	9.2
Boston	Spring	44.8	104.5	66.1	58.7	N.W.	10.0
	Summer	69.1	57.0	69.7	63.2	W.	7.4
	Autumn	51.0	103.5	71.3	60.9	W.	9.0
	Winter	28.0	82.5	71.4	54.8	N.W.	10.1
	Year	48.2	114.5	69.6	237.6	W.	9.1
Atlantic City	Spring	47.2	79.0	77.5	63.7	N.W.	11.3
	Summer	70.4	54.0	82.0	69.1	S.	8.5
	Autumn	56.0	84.0	78.8	63.9	W.	9.9
	Winter	33.4	78.0	79.9	58.3	N.W.	10.1
	Year	51.9	106.0	79.4	255.0	N.W.	9.9

Persons desiring to visit this section will find first-class hotels in the Chamberlin & Sherwood Inn at Old Point; the Augusta, in Hampton; the Warwick, in Newport News; the Monticello and Atlantic, in Norfolk; Hotel Monroe, in Portsmouth, and the Colonial Inn at Williamsburg. Among the seaside summer resofts are Buck-roe Beach Hotel, near Hampton, and the Virginia Beach and Ocean View Hotels, Near Norfolk.

PYLORIC STENOSIS IN INFANTS.*

By J. G. WILLIAM GREEFF, M.D.,
NEW YORK.

Pyloric stenosis in early infancy is still a rare disease. It is true there are now a number of cases of so-called congenital pyloric stenosis on record, but among the fifty or sixty odd cases reported, there are perhaps only thirty which were seen in infants. Since this condition has been known, it has been called congenital, but in looking over the cases reported, and judging from my own case, I have come to the conclusion that we have to deal with an acquired condition, not a congenital one.

Landerer, in 1879, was practically the first to report cases of congenital pyloric stenosis (I am using the term "congenital" when referring to cases reported under that name), and Maier, in 1885, gave an account of some twenty-one cases, observed post mortem. All of these were in adults. Since then, according to Monti, Williamson in 1841, and Davoski in 1842, have each reported one case. Hirschsprung, in 1888, was the first to observe this condition in infants, and then came Henschell, Finkelstein, Gran, Schwyzer, Thomson, Stern, J. H. Nicoll, and a number of others.

As yet, nothing is definitely known as to the possible origin of this condition. All authors, with the exception of one or two, as I shall show, are of the opinion that it is congenital. At any rate, Henschell's view, according to Stein, is that pyloric stenosis can occur through a family tendency to hypertrophies. This would point to the parents as a causative factor. In how far heredity can play a rôle has not been demonstrated, and I have been unable to find any case in which it has been known that any antecedent suffered from a similar condition.

A number of cases have been reported that got well, and it seems to me that the symptoms were very much like those of severe gastrointestinal catarrhs. The chronic cases of gastritis often show symptoms very much like those observed in the stenosis, especially when vomiting is very constant. However, a great many of the cases diagnosed as severe cases of gastritis may be cases of stenosis. In how far some of the constitutional diseases, as syphilis and tuberculosis, can be held accountable as a possible factor in bringing about this condition we do not know. Finkelstein says (I am not quoting him verbatim) that it is necessary first to consider whether we really have to deal with a congenital stenosis or with an acquired one; acquired as a result of secondary hypertrophy resulting from marked proliferating inflammation. One reason why it cannot be acquired, he thinks, lies in the fact that we have the sharply defined region of the hypertrophic pylorus in both directions. This, Maier defines as characteristic of a congenital stenosis, in contradistinction to the acquired form of stenosis, in which we have the hypertrophic gradually blending with the pyloric part. Another reason why this stenosis should be looked upon as congenital, Finkelstein gives in the fact that neglected infants, suffering for months with diseases of the digestive organs, have never shown any such excessive changes post mortem. He goes on to say: If such a gastritis could develop without any such predisposing and complicating moment, why can we not find a second paradigma? The proliferating gastritis in adults takes years to develop, and it hardly seems probable that such great changes could take place in a few weeks, or even months. However, it might possibly make a difference whether we have to deal with a rapidly developing stomach of an infant or with a fully developed organ in an adult.

*Read before the New York County Medical Society.

Pfaundler's theory, which I gathered from M. Schmidt's very interesting article: "Ueber Hyperemesis Lactentium; Ihr Verhältniss zur congenitalen hypertrophischen Pylorus-Stenose bezw. zum Pyloruspasmus und ihre chirurgische Heilbarkeit durch Ueberdehnung des Pylorus," is widely divergent from that of any of the other authors. He denies the existence of the congenital occurrence, and also doubts the presence of an actual hypertrophy in a real case of stenosis in infants. Pfaundler bases his assertions on the result of numerous exact anatomical examinations from autopsies on children. He makes a distinction, according to the state of contraction of the stomach muscles and the resulting form, between systolic and diastolic stomachs; stomachs which, after exhaustive histological and functional examinations, were found to be absolutely normal. An intermediate state between the two, he calls half-systolic stomachs. Now, his description of a systolic stomach is almost identical with that of the congenital cases. He found, in such systolic stomachs, the wall in the immediate neighborhood of the pyloric ring changed to a protruding swelling, thickened, rigid, and covered with folded mucous membrane.

The pylorus itself is very narrow, in consequence of the persistent contractions, and often not even permeable to a very small-sized probe. Water could be forced through only under high pressure. Very frequently the last portion of the wall projected for several millimeters into the duodenum so as to resemble the cervix uteri.

Microscopically, the abnormal thickness of the wall was shown to be due to an abnormal breadth of all muscle layers, especially the circular muscles, and they were well able, according to the histological picture, to stimulate a hyperplasia.

The dimensions which Pfaundler found in the normal stomach, when in this state of contraction, coincide exactly with the dimensions of the pylorus found by the writers on pyloric stenosis. Pfaundler found that the systolic and half-systolic stomachs, which would not even admit the passage of a very small cound, became permeable after the muscular rigidity relaxed. Pfaundler's résumé of the question is virtually the following: (1) The pylorus of absolutely normal stomachs can persist in a state of contraction, thereby giving it the appearance of a ring-like tumor of hyperplastic walls and narrowing the lumen of the gut, or even closing it absolutely. (2) Hirschsprung, Henshell, Gran, Stern, and others describe anatomical and histological pictures of congenital pyloric stenosis, which coincide with those of these systolic stomachs. (3) According to the observations of a number of authors and Pfaundler himself, there are conditions in early infancy which point to a stenosis of the pylorus.

I will now relate my case, in which it was possible for me to make the diagnosis intra vitam.

Child a boy, born November 25, 1902. Normal labor. For the first two weeks the baby seemed quite well, though the stools were not always satisfactory. Child was bottle-fed from fourth day on, getting two ounces every two hours, day and night, one part milk, two parts water. It started vomiting when two weeks old, became very restless; had temperatures, bad smelling stools. When I first saw the child it was twenty-three days old, crying constantly. It looked very puny; skin in loose folds. Stools and urine scanty; vomiting almost after every feeding; either immediately or two or three hours after.

On account of its illness the child had been put on various artificial foods. Upon examining the child, I found a poorly nourished infant, with very little adipose tissue; the skin, when picked up, stood in folds; fontanelle size of a ten-cent piece. Lungs and

heart normal. Liver slightly enlarged; spleen normal. The stomach was very much enlarged and distended. The lower curvature could be made out three finger breadths below the umbilicus. The intestines were never distended, after calomel had been given and the bowels were thoroughly irrigated. I stopped all milk and gave thin gruels, of barley water first and later of oatmeal. One-fifth of a grain of calomel was given for three doses. I washed out the stomach and ordered washing of the bowels twice a day, and stomach washing once every day. I saw the child again two days later, on the 20th of December; he still had a temperature of 102.6°; had not had any movement for two days; urine was very scanty, and vomiting continued. I ordered argentum nitricum 0.1 to aq. 90.0; a teaspoonful before each feeding. Bowel irrigation continued twice a day.

December 21, temperature normal; vomiting persistent; amount of mucus less. Stomach washing showed no bile; odor very sour. No free hydrochloric acid. Bowel irrigation showed mucous casts and some thick matter. For the next two days the temperature rose, with remissions, to 100.80, and went down, to remain at normal on December 25.

On December 24 I engaged a wet nurse; the child took the breast eagerly, but vomiting persisted just the same, coming in great gushes, either immediately after each feeding or after every two or three feedings. The child was very restless, crying almost constantly; it seemed hungry and would take the breast again immediately after vomiting, and then usually keep the food down. This also immediately after the stomach washings. The stools were very scanty. The weight of the child was 8¼ pounds at birth, and remained about the same until after it began vomiting, two weeks after it was born.

The vomiting at first came irregularly and at great intervals, but the child gradually lost weight and came down to between 6 and 6¾ lbs. in about ten days; from then until its death, when the weight was 6 lbs. 2 oz., the child lost weight slowly, and even apparently gained a little at times. And this was the reason that, although I had made the diagnosis of pyloric stenosis after seeing the child a few days, we did not consider an operation. My diagnosis was confirmed by Drs. Seibert, Caillé, and Holt. Dr. Holt advised operation, which was performed by Dr. Bull. The operation of gastroenterostomy was selected, and a posterior gastroentereostomy was done. Child died from shock twelve hours after operation.

At the time of the operation the pylorus was seen as a thickened mass, about 2½ centimeters long and 1½ in diameter. The boundaries of the tumor were sharply divided by a slight constriction from the stomach and duodenum.

I was able to perform the autopsy, and removed the stomach and part of the intestines. The intestines throughout were very small, more especially the small intestines, the large intestines having been seemingly dilated through the enemas. The stomach measured, in the greatest diameter, between the cardiac end and pylorus, 12 cm.; between the small and large curvatures 7 cm. The stomach was opened along the small curvature and found empty. Microscopically, the mucous membrane showed signs of catarrhal inflammation. The mucous membrane was folded, this being more marked at the pylorus. The stomach wall throughout was hypertrophied; this showed itself to a very marked degree at the pylorus, and a very small probe could hardly be passed through it. It could plainly be seen that the thickening at the pylorus was due to a muscular hypertrophy.

The microscopical examination confirmed our findings. It more particularly explained the condition. The glands seemed to be partly normal and partly hypertrophied to a moderate degree. The epithelial lining in a condition of more or less cloudy swelling; in some places so pronounced as to completely pale the nucleus. The fibrous connective tissue surrounding the glands it slightly hypertrophied and contains a varying number of inflammatory corpuscles. The muscles and connective tissue layers are in a condition of pronounced hypertrophy and hyperplasia, affecting both the circular and longitudinal muscle bundles to an almost equal degree, though perhaps in a larger number of specimens the circular muscle layer is more pronouncedly hyperplastic. A small number of inflammatory corpuscles is present throughout the layers. The fibrous connective tissue is partly in a condition of œdematous infiltration, while here connective tissue corpuscles and inflammatory corpuscles are fairly numerous. Capiliary blood-vessels are present throughout the specimens in rather large numbers, the endothelial lining in many being thickened.

When I first saw the child, it appeared to be suffering from a severe gastrointestinal catarrh. The continual vomiting, the temperature, the ill-smelling stools; in short, all the symptoms of a gastroenteric catarrh were present. Not having seen the child regularly at first, I could not gather, as I did afterward, anything characteristic about the vomiting. If this condition of gastroenteritis is present with a stenosis, these symptoms may, by predominating, prevent us at first from making a correct diagnosis. We often find scanty urine and stools in ectatic stomachs, and we often have marked peristalsis in catarrhal conditions, especially with hyperacidity, which, without a doubt, can lead to a temporary spastic stenosis. Fortunately, this is usually quickly amendable to the proper treatment. But if, after treating the catarrh, these symptoms persist, in the absence of temperature we may make the diagnosis of a stenosis. The symptoms of such a condition are: An enlarged stomach, determined by palpation or artificial distension, marked peristalsis, persistent vomiting after even small quantities of food are given. The food remains in the stomach an abnormally long time, often the entire quantity of several feedings. The stomach tube gives us valuable aid in this.

The absence of bile in the vomit; the constant absence of any distension of the intestines. The examination of the stomach contents shows, in almost all cases, the absence of free hydrochloric acid, absence of peptones, and usually the presence of acids, lactic and fatty acids. Unless a catarrh is present, there is little mucous. As to a differential diagnosis, there are hardly any conditions that need be considered.

Cancer of the pylorus has not been recognized, so far as I know, in very young infants, and I think we need only differentiate between this condition and a gastritis or gastrointestinal catarrh. I have indicated above how this may be done.

The prognosis is always a grave one. The mild cases will recover if the diet is regulated, and other proper measures resorted to, and any other complication, as catarrh, is removed.

If there is no quick response to palliative treatment, we may consider the advisability of an operation. It is fair to wait a week or so, but the weight must be carefully controlled, and the general condition of the child taken into consideration.

Of operations, we have the choice between Loretta's operation, the digital divulsions of the pylorus, gastroenterostomy, and the Murphy button. Cantly and Dent describe a few casse, in which pyloroplasty

was done, with good results. I, personally, do not think that we ought ever advise an operation. The case should be treated, I think, as in severe cases of hyperacidity in adults. Leave off all food by the mouth for a few days; wash out the stomach, give anti-fermentation medicines, alkalies, and when feeding is begun do so by the teaspoonful. Massage may be tried, and hot applications may be made over the stomach.

This case might, as I described it, be classified among those of congenital pyloric stenosis, but as I mentioned in the beginning of this article, I cannot agree to this. If I start with the fact that the child took nourishment for the first two or three weeks without any appreciable distress (in a great many cases reported the symptoms did not begin until a great deal later in life), had stools, and that the condition of the child at first was not a poor one, we can assume that a sufficient amount of chyme passed the pylorus to permit of normal nourishment, and that other conditions than the present supposition of an anatomical, so-called congenital stenosis, must be present. In my case there is no doubt in my mind that the stenosis formed during the last weeks of life.

Unfortunately, we know very little indeed about the physiology and the mechanism of the infantile stomach before birth, and during the first period after birth. If we take into consideration that the stomach passes first from a passive condition to a very active one, as it is called upon to do a great amount of work for the rapidly developing child, we are justified in assuming that a condition, as we find it in our case, develops in a short time. I have not made mention that through chemical influences, emanating partly from the secretions of the stomach, partly the food taken, or from an inherited disposition of the individual (reflex actions), conditions are brought about which may cause an increased working of the pylorus with the consecutive hypertrophy and stenosis. There are undoubtedly cases which might be considered as congenital; but I think only in so far as a congenital tendency to a narrowing of the pylorus is concerned, just as we might have it in other parts of the intestines, as, for instance, Schwyzer described it in his case, and that the full picture of a stenosis is brought about by a spasm from some such cause, as I have indicated above. Then, on the other hand, these causes in themselves would be sufficient to cause a pyloric spasm without any congenital tendency being present. Some of the patients mentioned in the literature had suffered for a period of varying length with acute or chronic gastrointestinal catarrh. How else can we explain the fact that a great many children acquire this condition later in life? If we take all these facts into consideration, I think we ought to admit that the etiology of a congenital formation will not hold good for a great many cases, and it is to be hoped that by careful observations of such other cases, and especially the consideration and study of the mechanism and chemistry of the stomach during the first period of life, we will gain further knowledge.

24 WEST NINETY-FIRST STREET.

THE MODERN VIEW AS TO THE ETIOLOGY AND TREATMENT OF ECZEMA.

BY ZAMA FELDSTEIN, M.D.,
NEW YORK.

ATTENDING PHYSICIAN IN THE DEPARTMENT OF GENERAL MEDICINE AT THE DEMILT DISPENSARY; ATTENDING PHYSICIAN FOR DISEASES OF CHILDREN AT THE NORTHWESTERN DISPENSARY.

THE causation of eczema has for centuries been a source of mental anxiety and controversy amongst the medical profession, arising from a misunderstanding of its inherent nature, cause, and progress. At the present day physicians, in respect to eczema, are divided into two classes, viz., those who maintain that eczema is a parasitic disease and those who claim that it is a purely constitutional ailment. Differing thus in this first and most important particular, it is small wonder that we have not heretofore been united as to the proper treatment, or that the pharmacopœia does not contain an effectual remedy. A modern dermatologist, assuming the parasitic theory as proven, has divided these parasites into twenty-three classes, but with this, at present, we have no concern, for we seek in the first place to satisfy ourselves that eczema is a parasitic disease, and then to find the most effectual method of curing it. Dr. J. A. Fordyce of New York, in his address as chairman before the Section on Cutaneous Medicine and Surgery, at the fifty-fourth annual session of the American Medical Association, at New Orleans, May, 1903, amply endorsed the parasitic theory of eczema, when he stated that "the constitutional causes of the disease are the contributing factors which favor the reaction in the skin; the real cause is probably the chemical products of the staphylococci. It is this toxin which is slowly generated from the staphylococci usually present in the skin follicles, and which under favorable conditions permeates the perifollicular tissues, that produces the phenomena which are called eczema."

While admitting that eczema may be primarily caused by a constitutional trouble or defect, the removal of such constitutional ailment is not in a large majority of cases followed by a cure of the eczema; this is, in my opinion, one of the many nails in the coffin of the "non-parasitic" theory, effectually destroying the argument that it is a purely constitutional trouble. Again, when the eczema seems, to all appearances, cured, the patient has a relapse, or, I should say, a return of the complaint; this does not prove the "non-parasitic" theory, but simply shows one of two things: either that the parasiticide used has not been sufficiently penetrating, or that the existence of some constitutional disturbance which is primarily responsible for the eczema, has set up a hyperæmia of the skin, with

the result that the parasites and their toxins become the exciting factor in the production of the eczematous lesion.

Various writers divide eczema into many classes, but in my opinion there are but two, *wet* and *dry*, but of these two classes many phases.

In cases of "wet" eczema, in which, through a mistaken notion of the physician, surface healing applications have been applied and the surface of the skin healed sufficiently to cover up the disease, the "toxin" which is generated by these parasites is accumulated under the skin and is liable to break out in a fresh place any moment. This discharge, through being dammed back, is now of a yellow mattery color, with an offensive odor, but upon the application of a penetrating stimulating parasiticide this discharge with its contained toxin, is thrown off by the stimulation of the skin and gradually becomes of a less yellow color, but still of a gummy consistency. This gummy consistency gradually gives way to a clear watery discharge which soon exhausts itself, much to the patient's satisfaction and comfort. In passing, I might state that while the discharge is of a yellow color there is danger of inoculation, thus proving again the parasitic theory, but when the discharge becomes of a clear color all danger of contagion is passed. The great mistake we have hitherto made, is in applying too early in the treatment surface-healing remedies, which have the effect of covering up the disease, only to let it break out again in a more virulent form.

Another mistake has been the use of a grease as the basis of all our ointments; moreover an animal grease has been invariably employed, and this has had the effect of feeding the parasites, while the other constituents of the prescription generally used, such as oxide of zinc, have healed and hardened the surface so that any penetrating parasiticide of the pharmacopœia is necessarily retarded in its action.

I hold that eczema is a parasitic disease, and the only thing necessary to produce an eczema is the congestion of the skin, which may be produced by constitutional ailment or defect, or by outside influences, such as cold or chill; and further I am of the opinion that the parasite, having been once called into activity, as it were, the primary cause can be cured, but the effect, *i.e.* the parasite, remains until destroyed by a parasiticide sufficiently penetrating to establish contact, and sufficiently stimulating to restore the skin to its natural activity.

While stating that, in a large percentage of cases, the local application of a penetrating, stimulating parasiticide is all that is necessary to complete a cure of the eczema, I do not want to deprecate the constitutional treatment, but the latter treatment is only useful as an adjunct; for instance, in the case of what has been called a "neurotic" eczema, it is necessary by constitutional treatment to restore the nervous system, but complete restoration of the nervous system has not, in a large number of cases, been followed by a cure of the eczema, and that is why I assert that where constitutional treatment is indicated, it is only necessary as an adjunct to the local treatment.

Dr. J. A. Fordyce of New York writes: "It is easy to say that eczemas are produced or modified by gouty states, indigestion or some indefinite general disturbances, but the more closely we study our cases in the light of modern knowledge as to possible sources of infection the fewer cases are met with which cannot be better explained by some local toxic or microbic irritant."

Malcolm Morris, in his work, "Diseases of the Skin," while not accepting the parasitic theory of eczema as proven, admits that "it is impossible to believe that parasites known to possess certain pathogenic properties can be present in such numbers as they have been proved to be by competent observers without having a considerable effect on the character and severity of the disease."

Be that as it may, the fact nevertheless is evident that in every case of eczema an effective parasiticide is absolutely necessary, and when a penetrating stimulating parasiticide is employed, success follows the treatment. Then, again, we must take into consideration the unwritten law of cause and effect; we can cure the eczema caused primarily by a varicose vein by a stimulating, penetrating parasiticide, but unless we continue the application of the parasiticide as a preventive, or remove the primary cause (the varicose vein) the patient is bound to have a return of the eczema. I have recently been using a mixture of Juniperus oxycedrus, stavesacre, Pinus silvestris, and Eugenia caryophyllata, prepared without any animal fat. This is a parasiticide, capable of deep penetration, and at the same time harmless to the tissues. I have found it so deeply penetrating that the itching is stopped upon the first application, and, in time, repeated applications permanently remove the irritation; eventually all the cases under my control have yielded to this treatment.

In applying a stimulating parasiticide, it is necessary to commence with weak applications so as to avoid over-stimulation, for the simple reason that, while we can cure a natural eczema, by over-stimulation we produce what has been incorrectly termed an "artificial eczema." The latter, being a non-parasitic ailment, can soon be cured by ordinary non-parasitic and non stimulating remedies or by non-stimulating parasitic applications. The parts most liable to over-stimulation are the genitals and the scalp. Malcolm Morris, in the book above mentioned, says: "In dealing with eczema the beginning of therapeutic wisdom is to clear one's mind of the notion that arsenic or any other drug is a specific. The practitioner must learn not to look upon it as a fixed law that internal remedies are to be given in every case. As a general rule, indeed, the less drugging the better. But if internal remedies have to be employed, they should be given only for a definite purpose and in accordance with definite indications. Although internal medication may be a useful adjuvant in the treatment of eczema, the practitioner who, from a mistaken belief in the constitutional nature of the disease, trusts entirely thereto will find he is leaning upon a broken reed. Eczema, being in a large proportion of cases of parasitic origin, can be cured only by appropriate local remedies, and in seborrhœic cases, when the patient's general health is sound, no other treatment is required. As regards diet, the practitioner must, in the first place, clear his mind of the superstition as to this matter which is so strongly implanted in the mind, not only of the public, but of a section of the medical profession, especially those of the older school. Their ideas on the influence of diet in eczema are founded on the belief that every skin eruption requires to be treated constitutionally. This notion, as has been seen, is entirely erroneous, and I cannot help suspecting that it has arisen at least partly in consequence of the ignorance which prevailed until lately as to the action and proper method of using local remedies."

Prof. Niels Finsen of Copenhagen has been awarded the Cameron prize, bestowed by Edinburgh University, for the most important work in practical therapeutics during recent years.

A METHOD FOR PREVENTING THE PAIN FOLLOWING CLAMP-AND-CAUTERY OPERATIONS FOR HEMORRHOIDS.

By HOWARD LILIENTHAL, M.D.,
NEW YORK.
ATTENDING SURGEON TO MT. SINAI HOSPITAL.

It is well known that for several days after the usual clamp-and-cautery operation pain and œdema contribute greatly to the distress of the patient. For the last three years I have adopted a method which reduces these disagreeable symptoms to a minimum. The point is a minor one from a technical point of view, but it is of great surgical importance.

Immediately after the clamping and burning have been completed, six or seven radiating incisions through the skin, well into the subcutaneous tissue, are made with scissors. There is rather smart bleeding, which, however, is easily checked by a little pressure and a dry dressing. In six hours a wet dressing may be applied. There is a free flow of serum from these incisions for the next day or two. Œdema, with its danger of infection is absent, and the patient feels perfectly comfortable.

This method has been thoroughly tested by the writer and a number of colleagues at the Mt. Sinai Hospital and has given great satisfaction, robbing the after-treatment of the clamp-and-cautery operation of its greatest terrors.

766 Madison Avenue.

The Wounded in Modern Naval Warfare.—In a report submitted to Surgeon-General Rixey, Dr. H. D. Wilson of the *Vicksburg*, who aided the wounded on the Russian cruiser *Variag*, says: "The greater percentage of the wounds were of a serious nature, as all had been caused by the explosion of large shells (from eight to ten inches). Of the wounds dressed nearly all were in the lower extremities, which is accounted for by the fact that while many were hit in various parts of the body, the pieces of shell, etc., were so large as to cause death whenever they struck the body or head. No attempt was made to perform operations, and as soon as dressings were applied the wounded were put in boats and taken to some of the foreign ships, as the Russian captain intended to leave his ship and sink her. Many of the wounded died later from the operations, and from the direct effects of the wounds, as the parts were so damaged as to make an operation absolutely hopeless. I think the engagement showed that it will be impossible to attend the wounded during an engagement between modern ships, unless the number of medical attendants is tremendously increased. With the present allowance the wounded would be obliged to take entire care of themselves until the fight was over. In this battle the ships were from 3,000 to 7,000 yards apart, and actual firing lasted not over twenty-five minutes, yet over one hundred men were disabled. It also must be taken into consideration that here the main battery only was used, the ships not being hit once by rapid-fire projectiles."

A Case of Myelogenous Leukæmia with Disappearance of the Splenic Tumor and Return of the Leucocytes to Normal.—Charles E. Simon and Dr. George T. Campbell report this case which came under their care. The patient's health had been good until 1901, when she was subjected to a severe mental strain. She began to have indigestion and palpitation and soon noticed pain and some bulging below the ribs on the left side. There was also severe pain in the right shoulder, and some headache, especially on the left side. The bulging increased till it extended down to the left groin. It felt quite hard, but was not tender. She lost weight and grew weak, and began to have pain in the legs which kept her awake at night. When she consulted a physician, the enlarged spleen was discovered. Blood examination showed 1,700,000 red cells and 350,000 leucocytes. A little later the hæmoglobin was found to be 56 per cent. Fifteen per cent. of mast cells were present. There were marked anisocytosis and poikilocytosis and a considerable degree of polychromasia. Hæmoblasts were quite numerous and nearly all undergoing hæmocytolysis. Isolated megaloblasts were seen. Granular degeneration was not observed. The patient was put on Fowler's solution. She improved markedly. Nearly a year later, the hæmoglobin was 75 per cent., the red cells numbered 3,984,000, and the leucocytes 4,500. The spleen is barely palpable on deep inspiration. Aside from the mast cells, 11.5 per cent., one would scarcely think of myelogenous leukæmia without a knowledge of the past history. Bence Jones albumin was never detected. Notwithstanding the remarkable tolerance of arsenic, for she had been taking 26 drops of Fowler's solution *t.i.d.*, the writer is tempted to question the relation between treatment and result as that of cause and effect.—*The Maritime Medical News.*

Parasyphilitic Disorders.—Archibald Church declares that the parasyphilitic disorders are not marked necessarily by any of the active lesions of syphilis. The gummy processes are no part of the parasyphilitic disorders, and similarly the parasyphilitic disorders are not amenable, in the ordinary sense, to antispyhilitic remedies, the essential lesions consisting in these cases of degenerations. He limits the discussion to tabes and paretic dementia. In all recent statistics, evidence of syphilis is obtained in from seven to nine out of ten cases of tabes. Erb, in a recent compilation of 1,100 cases, finds syphilis to have been present in something over 90 per cent. Fournier's results agree with this estimate. The symptoms of tabes and paretic dementia appear in the majority of cases from ten to fifteen years subsequent to the initial sore, but may appear as early as the first year, or in thirty-five to forty years ofter primary infection. There is no period in the life history of any syphilitic in which these dreadful disorders may not develop. So-called mild cases, which consequently are not well treated, seem to preponderate in the histories of the parasyphilitic disorders. Nevertheless, individuals who have been carefully, thoroughly, and persistently treated for several years, sometimes develop tabes and paretic dementia. All cases of early paretic dementia and juvenile tabes are based upon syphilitic parentage. The great majority of cases of tabes and paretic dementia develop in the third and fourth decade of life, with scattering cases in subsequent and previous years. As to sex, there is about one case of female tabes and female paretic dementia to ten or twelve in males. The proportion of syphilis is the same. There is a race tendency or liability to these disorders, and a racial immunity. Orthodox Jews are practically free. So is the highland Scotchman, and the peasant Irishman. The negro and Egyptian are particularly subject to syphilis, but are practically immune as far as tabes and paretic dementia are concerned. Clergymen furnish relatively the least number of victims. Certain alleged causes of syphilis are cold, rheumatism, over-exertion, alcoholism, acute fevers, venereal excesses, and trauma. Some eminent authorities absolutely deny the relation of trauma to tabes and paretic dementia, while others do not entirely exclude it, and believe that in conjunction with syphilis it may undoubtedly play an active part. From a practical standpoint, every individual who has paretic dementia or locomotor ataxia should be looked upon as a syphilitic. Nine out of ten parasyphilitic cases may be attributed to specific infection, and the tenth case is not above suspicion. Sometimes the vigorous use of antisyphilitic remedies in these disorders induces a recession of the conditions and sometimes an apparent cure. And even some of the late degenerative processes in paretic dementia and locomotor ataxia may be brought to a standstill by the vigorous use of mercury.—*The Chicago Medical Recorder.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51, FIFTH AVENUE.

New York, August 27, 1904.

THE LESSONS OF THE BUTLER EPIDEMIC.

MISFORTUNES are often blessings in disguise, and events which appear at the time to be almost irreparable disasters, frequently prove to be but the mainsprings of future success and the causes of a better order of things. The most valuable lessons have been taught by adversity. Dr. Benjamin Lee, Secretary State Board of Health of Pennsylvania, in an article contributed to the first number of *Sanitation* endeavors to drive home the force of this dictum, and, with the recent epidemic of typhoid fever in Butler as a text shows the lessons which should be learned from such a calamity.

The outbreak of typhoid fever in Butler was in many respects unique in the history of occurrences of a similar character. Few, if any, epidemics within the memory of the present generation developed so rapidly, or were attended with so fearful a mortality. This, at first sight, seems curious, for, as Dr. Batt, Quarantine Officer at Large, representing the State Board of Health, says in his report on the Butler epidemic: "There are comparatively few communities in the State in which greater care had been taken, or a larger amount of money spent in comparison to population and resources, for procuring and maintaining a pure, wholesome, and sufficient water supply than Butler." When, however, the matter is more closely looked into, facts come to light which explain why the typhoid-fever epidemic in Butler broke out so suddenly and raged with such deadly results.

Dr. Lee states that the first indictment must be brought against the Legislature of the State, which, in providing for the sanitary organization of municipalities and townships, has made its laws on this subject too often simply permissory, not mandatory. Instead of declaring that a borough board of health may adopt and enforce a system of registration of vital statistics and contagious diseases, it should have declared that a board of health shall adopt such a system; and instead of declaring that a school board of a township may perform the functions of a board of health for a township, it should have declared that the school board shall in every township perform such functions.

The writer also thinks that the physicians of Butler were culpable in that they neglected to comply with the requirements of their Board of Health and of the State Board, and failed to report their cases of typhoid fever.

But the Water Company of Butler must bear the heaviest share of the blame and responsibility both for their sins of omission and commission. First, in constructing dams without proper corewalls or adequate spill-ways, which would enable them to withstand an unusual rainfall. Second, in failing to maintain a patrol of their water shed, and thus to discover and eliminate sources of pollution of their streams and reservoirs. Third, in failing to notify the Board of Health and the citizens of Butler in advance, when they were about to pump polluted water into their distributing reservoir, so that the precaution of boiling the water might have been taken. A most serious sin of omission on the part of the Water Company and of which—according to Dr. Lee—it is still guilty, is that there is no provision for storing its filtered water.

The writer is of the opinion that the lessons furnished by the Butler calamity are as follows: Firstly, the necessity for enactment by the next Legislature of a law establishing a health authority in every county and in every township, amenable to the central health authority, but possessing ample power to enforce its own regulations. Secondly, the adoption of legislation compelling the reporting of deaths and communicable diseases in all cities, boroughs, and townships, and the registration of the same at the Central Bureau of Vital Statistics. Thirdly, the passage of laws for supervising the construction and inspection of all dams and of all water-works. Fourthly, the moral obligation resting upon physicians, entirely apart from legislative enactment or compulsion, to report to the health authorities with the utmost promptness every case of communicable disease occurring in their practice. Fifthly, the danger of using any surface water without filtration. The company or municipality which furnishes such water does so at the risk of the lives of its patrons or constituents, and should be held to strict accountability for the results.

Municipalities of the United States are, as a rule, far too careless as to their water supply, and although the fact is beginning to be recognized that a pure supply of water is of the first importance, indeed is absolutely essential to the preservation of the health of a community, the truth of this does not as yet appear to be appreciated at its full significance. There are many cities of great wealth and size in this country in which typhoid fever is frequently rife, and may almost wholly be attributed to a defective water-supply. In Europe, and especially in Germany and in Great Britain, matters in this respect are far better managed. There would appear to be little doubt that it would be in the best interests of the public health if State legislation were to insist that the water supply system of towns be so conducted that pure water might be guaranteed with more or less certainty.

One point stands out clearly in a study of the Butler epidemic, namely the value of filtration. The filter plant at Butler was but a small one, yet while it was in use it protected the health of the community. As soon, however, as the filter ceased to act and the contaminated water was served to the inhabitants of Butler, the epidemic set in with deadly virulence. The demonstration as to the efficacy of the filtration method was conclusive. The calamity at Butler should be taken to heart and acted upon in a practical manner. The question of a pure water

supply rests with the people, and if the inhabitants of any town insist upon being served with unpolluted water at all times, in the end their insistence will have the desired result.

TUBERCULOSIS AMONG HEBREWS.

Nearly all sociologists and demographers agree in the assertion that Jews, even those living in the crowded and often filthy "ghettoes" of London, New York, and Chicago, enjoy a comparative immunity from tuberculosis. For example, Billings, in the statistics prepared for Bulletin 19, of the Census of 1900, gives the death rate from tuberculosis among Jews as only 22 per 100,000 living, although the rate for the entire country was 145.85 per 100.000. For the six years ending May 31, 1900, Billings records an annual death rate from tuberculosis in New York City of only 76.72 per 100,000 living among the Hebrew population, while that among the Irish reached the enormous figures of 645.73. Fishberg, in a comparative study of the mortality statistics in different parts of this city (*American Medicine*, November 2, 1901) shows that the annual mortality from tuberculosis during the three years from 1897 to 1899 was, in the wards inhabited chiefly by Hebrews, at the rate of 163 per 100,000 living, while in a ward inhabited chiefly by Irish and Italians the death rate from tuberculosis was 565 per 100,000.

That there is a fallacy somewhere in these figures seems very probable, for there is nothing in the mode of living or the surroundings of the Jews that would seem adapted to give them greater resisting power against pathogenic microorganisms, unless it be that the unspeakably wretched conditions under which they have lived for so many generations in Eastern Europe have, by a process of the survival of the fittest, resulted in a racial immunity. In an article on "Tuberculosis in the Jewish District of Chicago" (*Journal of the American Medical Association*, August 6, 1904), Dr. Theodore B. Sachs presents some figures showing that the degree of immunity against tuberculosis enjoyed by Hebrews is not nearly so great as has been supposed, and he says that, contrary to the popular general belief, the disease is very common among the poor of the Jewish population. The district studied by him holds a population of about 31,000, of which 22,500 are Hebrews, and a central block in this district, in which a special house-to-house investigation was made, contains a population of 2,007 Jews and 214 persons of other races. In this district the annual death rate from consumption, estimated from the figures for the six months ending November 1, 1903, was, among the Jewish inhabitants, 151 per 100,000, and among the non-Jewish population, 502 per 100,000. In the central block the estimated annual death rate from tuberculosis, based on the statistics for six months, was 281 per 100,000. Dr. Sachs says, "these figures would naturally lead to the conclusion that mortality from tuberculosis among Jews is comparatively low and that Jews enjoy a certain immunity from this disease."

The weak point in all these comparisons drawn from mortality statistics is that the Jews have a firmly rooted belief in climate as the only cure for consumption, and the instant the disease attacks them they run to a place of safety. "Men and women in very destitute circumstances will sell all their belongings and without second thought start on a journey to some of the distant Western states." The consequence of this is, Sachs says, "that only a fraction of the Jewish tuberculous poor die in the districts in which they contracted the disease, and consequently any conclusions concerning the prevalence of tuberculosis among Jews, based only on the rate of mortality, are necessarily erroneous to a considerable extent."

This contention is strengthened by a study of the ages of those dying from tuberculosis in the Jewish district of Chicago. Of the 51 deaths which occurred during the period of collection of statistics, 26 were of children under fifteen years of age, while in the usual period of greatest mortality, that between twenty and forty years, there were but 10 deaths. The deaths of children were in a large measure due to tuberculous meningitis, and the small number of adults dying from tuberculosis is explained by the emigration of those in the early stages of the disease. That this assumption is well founded is shown by the morbidity statistics of the Jewish district, which were very carefully collected for the eighteen months ending November 1, 1903. In this period 840 Hebrews with tuberculosis applied for hospital and dispensary treatment, and of this number 589 came from the Jewish district. One hundred and ninety-two of these patients were under fifteen years of age, and 383 were between twenty and forty years of age, figures which offer very strong proof of the correctness of Dr. Sachs' assertion that the alleged immunity of Jews against tuberculosis does not exist—at least in any such degree as has been believed. The result of his investigation, Sachs holds, is "the inevitable conclusion that tuberculosis is very prevalent among the Jewish poor, that unsanitary conditions of home and factory life are chiefly responsible for its widespread occurrence, and that tuberculosis mows down its victims regardless of race or nationality."

Subcutaneous Injections of Olive-oil for Nutrient Purposes.

It is generally agreed that the problem presented in the treatment of tuberculosis deals largely with the question of the general nutrition. The course of any given case can best be followed by a study of the body-weight. For this reason it is of the utmost importance that the nutrition of the patient be maintained and improved in every manner possible. To this end provision should be made not alone for a generous supply of fresh air and sunshine, but also for the assimilation of a large measure of force-generating and tissue-building food.

The prognosis of tuberculosis is in no small degree related to the condition and the activity of the gastrointestinal tract but unfortunately these often become impaired in the course of the disease, and then physical deterioration and advance of the morbid process are likely to become marked. Under such circumstances, and sometimes even apart from them, it would be advantageous if food could be introduced through some other channel. The recommendation that nutriment be administered by way of the skin or through the subcutaneous tissues is not a new one, but it has scarcely proved feasible and susceptible of more than exceptional application. In line with this thought subcutaneous injection of sterilized olive-oil has

been proposed (Keyes, *Canadian Journal of Medicine and Surgery*, June, 1904), and from the employment of which in nine cases of pulmonary tuberculosis diminution in cough and night-sweats, and increase in strength and gain in weight have been reported. The injections were made over the shoulder-blades on successive days by means of an aspirating syringe, the piston being reversed with a thumb-screw. Twelve c.c. were introduced on the first and second days, 24 c.c. on the third and fourth days, 40 c.c. on about the fifth day, and, unless unpleasant or inconvenient symptoms arose, the amount was gradually increased to the tolerance of the patient. Poorly nourished patients will, it is stated, sometimes assimilate as much as 200 c.c. daily.

Of course no definite conclusion can be formed from the small number of cases reported, but the method commends itself on account of its apparent freedom from risk; and by reason of the promise it holds out it would seem to be at least deserving of further trial. It is thought that the oil injected undergoes digestion, in part as a result of the activity of the blood, particularly the leucocytes. Other appropriate therapeutic measures should naturally not be neglected.

Medical Department of the Japanese Army.

The censorship of the Japanese army has been so strict that little is accurately known of the occurrences in the war now raging in the Far East. It is known that battles have been fought and that the loss of life on both sides has been heavy, but all details are lacking. As to the work of the Medical Departments of both the Russian and Japanese armies, although it may be assumed to have been heavy, the outside public has been kept ignorant of the facts.

The Japanese Army Medical Department is like the rest of that body, well-organized and well-equipped and has doubtless been able to cope with its arduous duties in a satisfactory manner. The *Journal of the Association of Military Surgeons* for August has an article on the Medical Department of the Japanese army. The paper in question states, in part, that officers of the army medical service are recruited principally from students of the medical school or the university, who are required subsequently to undergo a course of instruction at the Military Medical School. One-year volunteers, who are licensed to practise medicine or to dispense, and men between the ages of twenty and thirty who have matriculated at the military medical school, may be appointed surgeon probationers and promoted to third-class surgeons. Medical officers are classed as non-combatants, but have a relative military rank, the highest grade being that of lieutenant-general.

In peace time the headquarters medical personnel of each division consists of one principal surgeon, two surgeons, and nine medical subordinates. In war time, to each mobilized division is attached a medical detachment, consisting of detachment staff, two sanitary (or bearer) companies, and six field hospitals.

There are also reserve hospitals, and auxiliary hospitals may be established when required. Stationary hospitals are established at certain bases. The war establishment of a mobilized division is as follows:—Medical sanitary detachment: officers, 13; non-commissioned officers, 60; privates, 330. Total, 403. Animals: pack, 40; riding, 10. Total, 50. Six field hospitals: officers, 42; non-commissioned officers, 54; privates, 600. Total, 696. Animals: pack, 300; riding, 42 Total 342.

The Menace of the House-fly.

The summer time, especially in cities, is fraught with much danger to life and health. Children suffer in particular during the hot weather, and it behooves Boards of Health and parents to take all possible precautions to safeguard the lives of the young at this period of the year. The ordinary house-fly, over and above the annoyance created by its presence, has been proved to be a real source of danger. Experiments undertaken during the South-African and Spanish-American wars demonstrated conclusively that flies were important agents in the conveyance of typhoid fever. For this reason flies should be kept out of houses and destroyed when possible. A writer in *Sanitation* for July advises boards of health to take the following measures: (1) To use the most stringent means to secure the perfect disinfection of all discharges from typhoid-fever patients. (2) To urge upon people the necessity of screening their dwellings, protecting all foods, and explaining the dangers incurred by not doing so; they should be taught to regard flies with suspicion. (3) As flies breed most abundantly in manure piles and the droppings from horses, regulations should be adopted and enforced compelling the proprietors of livery stables and private owners of horses to cover or screen their stable refuse in such a manner that flies cannot have access to it. Germicides, chloride of lime or similar preparations that will destroy the eggs of the house-fly, should be used freely and frequently in manure pits and around stables. (4) Unusual care should be taken to clean thoroughly and frequently the public streets, removing all droppings from horses and treating street cleanings at the dumping grounds in the same manner as at public or private stables. The above advice is timely, and should, if followed, prevent much sickness.

News of the Week.

Laboratory of the Illinois State Board of Health.—A building has been secured in Springfield, Ill., for use as a laboratory of the State Health Board. The laboratory is equipped with all the apparatus for bacteriological and chemical examinations necessary in the sanitary work of the board, and will add materially to the efficiency of the board in the investigation of water supplies and in the prevention of communicable diseases. The laboratory is especially needed on account of the vigorous campaign instituted by the board some time ago against consumption and which is now being conducted in every county in the State. The laboratory will be open at all times to the physicians of Springfield and Sangamon county, who will have free use of the scientific appliances and equipment.

A School in Philanthropy.—Encouraged by the success of the summer school in philanthropic work which has just completed its seventh term, the officers of the Charity Organization Society have determined to establish a permanent school to train men and women in the practical conduct of charitable and sociological work. There will be a series of two hundred and sixty lectures, divided into seven courses, under the titles of General Survey, the State in Its Relation to Charity, Child-helping Agencies, the Care of Families in their Homes, Preventive Social Work, Hygiene, Hospitals, Care and Prevention of Disease, Treatment of the Criminal, Reformatory Work, Probation, etc. The fall term will open October 3, and continue until December 22. There will be winter and spring terms, closing finally with examinations on June 1. Be-

sides the lecture course, the members of the school will have practical work in local charitable societies and institutions—laboratory work and training at first hand. Membership in the school will be limited to persons who have had at least one year's experience in charity work, college graduates who have had one or more years' work in social economics or kindred subjects, and senior students in theological and medical schools. The director of the school is Mr. Edward T. Devine, Secretary of the Charitable Organization Society.

New Hospital Buildings at St. Louis.—A bond issue of $9,000,000, subject to the approval of two-thirds of the voters of the city at the fall election, is provided for in a bill which was introduced in the house of delegates in that city. Part of the funds so raised are to be used for the construction and extension of hospitals for chronic and convalescent cases, for a new female hospital, and for the construction and extension of the hospital for the insane.

Medical Inspection of Schools.—Health Officer Clark W. Davis of Cincinnati is devising a plan for the medical inspection of the public schools of that city. His idea is that the teachers of the schools should be instructed to watch their pupils carefully, and when one gives any evidence of being ill to have the child examined by a district physician. For instance, if it be noted by the teacher that a child has sore eyes, is nervous or feverish, she will have the child sent to the office of the principal. It is the purpose to have a specific day set aside for a district physician to call at the schools, when he can examine all the pupils who are thought to be sick. There are about fifty schools, and there are twenty district physicians, so that the visits could be made twice or three times a week without an increase in the force. If the district physician should conclude that the child is sick, he will send it home with a note to its parents with the advice that a physician be consulted. The sanitary condition of the schools would also be looked after.

Examination for Interne in the Hospital for Contagious Diseases.—An examination of applicants for the position of Assistant Physician in the hospitals for contagious diseases connected with the Department of Health will be held at the Willard Parker Hospital, at the foot of East Sixteenth Street, on September 1 and 2, 1904, at 2 P.M. Applicants should have had a general hospital training, or practical experience in the care of infectious diseases. The positions are salaried. Examinations will be both written and practical, and will include general medicine, surgery, pediatrics, bacteriology, pathology, and infectious and contagious diseases. Application should be made to the Secretary of the Department of Health, Fifty-fifth Street and Sixth Avenue.

Opening of the Policlinico at Rome.—Those who attended the sessions of the International Medical Congress in Rome in 1894 will perhaps be surprised to learn that the magnificent "Policlinico" where the section meetings of the congress took place has only just been opened. But things move slowly in the Old World—so slowly that when at last it was decided to open the institution it was necessary to spend a large sum of money in making the buildings habitable and in repairing the damage they had inevitably sustained by being closed and unused for so many years. The hospital was opened for the reception of patients on August 2. The hospital proper consists of ten pavilions, each capable of receiving eighty-four patients, a special wing for infectious cases, and a central building for administrative purposes. There are also buildings for clinics of Medicine, Surgery, Obstetrics, Gynecology, Dermatology and Syphilography, Ophthalmology, Pediatry, Oto-rhino-laryngology, Special Medical and Surgical Pathology, and Neurology. In all there are twenty-six buildings. The following professors, each with two assistants, have been appointed: On the surgical side, R. Bastianelli, T. Ferretti, and R. Alessandri, and on the medical side T. Ferruccio, A. Zeri, V. Ascoli, U. Archangeli, E. Rossoni, G. Bastianelli, V. Pensuti, and T. Gualdi.

Fatal Mistake of a Drug Clerk.—A drug clerk in St. Louis has been held for murder in the fourth degree by the coroner's jury, and the proprietor held on the same charge on account of the death of a woman who sent to purchase cream of tartar and was given tartar emetic, labeled cream of tartar. The woman took a teaspoonful and died before physicians could counteract the effect. At the inquest it developed that the clerk was an unlicensed druggist.

An Educated Horse.—Considerable interest has, it is said, been aroused among psychologists in Berlin by the performances of a trained stallion. A report states that the horse, besides adding, subtracting, multiplying, and dividing, does examples involving several of these operations, finds square numbers, and not only repeats what he has been taught, but solves fresh problems, showing a grasp of the principles of arithmetic. "The stallion also forms little sentences, remembers them next day, and knows twelve colors and shades, giving their corresponding names. He distinguishes musical tones, indicating where they are situated on the chromatic scale, and picks out discords, designating which tone to omit in order to restore harmony." The summer is evidently a "silly season" in Berlin as well as elsewhere, or else the Prussian minister of education and various professors at the university, who are said to be amazed at the wonderful mental powers of the horse, are remarkably gullible. The horse communicates by a system of hoof beats designating the letters of the alphabet, just as many other similarly trained animals to be seen at almost any circus or animal show in this country. His master is perhaps a little more skilful in concealing from the observers the sign given to the horse when the number of hoof beats has reached the required letter of the alphabet.

Treatment of the Wounded by the Japanese.—The Associated Press cables a long interview with Dr. Louis L. Seaman of this city who has recently arrived at Che-Foo from Manchuria. In speaking of their method of treating the wounded, he says that the Japanese are giving proof of the benefits to be derived from the non-interference with wounds on the field, where they content themselves with the application of first-aid bandages and antiseptics, leaving the more serious work to be done in the hospitals at home. This course is followed except when their is danger of the wounded man bleeding to death or when his condition is very precarious. The result of this practice has been that many men suffering from bullet wounds at the front are nearly well when they reach Japan. In one hospital ship returning to Japan from the front there were 2,200 wounded men, and there was not a single death on board during the trip. There have not been more than three deaths among the wounded who have been returned to Japan after having received first-aid treatment only. Russian wounded captured by the Japanese have been treated in a similar manner, and the recoveries among these men are scarcely less in proportion than among the Japanese.

Commers in Honor of German Scientists.—The Union of Old German Students in America will entertain the German scientists who attend the St. Louis Congness of Art and Sciences at a "commers" in Arion Hall, on October 8. Most of those who will be guests of the union are medical men. The president of the union is Dr. Carl Beck; the secretary, Dr. A. Ripperger, No. 50 West One Hundred and Thirtieth Street, New York.

The Continental Anglo-American Medical Society.—The annual luncheon of this society was held at the Clarendon Hotel, Oxford, July 28, during the week of meeting of the British Medical Association. Dr. William Osler, honorary president of the society, presided. Eighteen members, an unusually large number, sat down to the luncheon.

Bequest to a Hospital.—By her will, filed in the surrogate's office in this city a few days ago, the late Cornelia A. DeWint bequeathed to St. John's Riverside Hospital at Yonkers $10,000.

Contest Over a Hospital.—The courts have been invoked by sisters of the Third Order of St. Francis to compel the Windsor Trust Company to deliver to them $70,000 paid by the Pennsylvania Railroad Company for the old St. Elizabeth's Hospital in Thirty-first Street, which was on a part of the site of the new terminal station of that road. A new hospital was opened after the old one was torn down, but the church authorities claim that it is now under their direct control, and that consequently the money should be paid to them.

The American Roentgen Ray Society, now in the fifth year of its existence, under the presidency of Dr. James B. Bullitt of Louisville, Ky., meets in St. Louis on September 9, 10, 12, and 13. The meetings will be held in the Louisiana Building, on Vandeventer Avenue, facing the western entrance to Vandeventer Place. The sessions will be in the forenoons only, affording visiting members an opportunity to attend the World's Fair in the afternoons. An important part of the meeting will consist in demonstrating apparatus and improved methods in radiography, skiagraphy, and allied subjects. Dr. Joseph Grindon is chairman of the local committee.

The French Surgical Congress will hold its seventeenth annual session in Paris in the week beginning October 17, under the presidency of Dr. S. Pozzi. The following are the subjects for discussion: (1) The Surgical Treatment of Cirrhosis of the Liver, to be opened by M. Monprofit of Angers; (2) The Semeiological Value of Examination of the Blood in Surgery, to be opened by M. Tuffier; (3) Traumatic Separation of the Epiphyses, to be opened by M. Kirmisson.

Assistant Physicians to Insane Asylum at St. Louis.—Doctors F. L. Whelpley and William J. Loler have been appointed assistant physicians at the St. Louis City Insane Asylum to fill vacancies caused by resignation.

The French Urological Association will hold its eighth annual meeting in Paris on October 20, 21, and 22, immediately after the sessions of the French Surgical Congress. The subject announced for formal discussion is "The Indications and the Therapeutic Value of Prostatectomy."

The Philippines Menaced by Epidemic Diseases.—A despatch to *The Globe* says that apprehension is felt by officials of the U. S. Public Health and Marine Hospital Service regarding the great danger the Philippines are in from invasions of the plague and cholera. It is said that at no time since the American occupation have the islands been threatened by quarantinable diseases from so many points as now. Plague is epidemic in southern Formosa and at Hongkong and Amoy. Hongkong is a source of great danger to the Philippines, as traffic between that port and Manila is heavy and the run for steamers is but two days. Cholera has appeared at Hongkong in addition to the plague, and also at Saigon, which carries on a great rice trade with the Philippines. Plague has long had a foothold in the islands in spite of every effort to stamp it out, and smallpox is prevalent.

Opening of Addition to Hospital.—The new $140,000 ward addition to the Illinois Western Hospital for the Insane, Watertown, Ill., was informally dedicated August 2, and 300 new patients from Lee, Ogle, and Stevenson Counties were installed. The new structure is said to increase the capacity of the institution to 1,200 patients.

Anti-spitting Ordinance.—A new ordinance was recently passed by the Seneca (Ill.) City Council imposing a fine of not less than $3 nor more than $25 for any person caught spitting on the sidewalk.

Smallpox in Chicago.—There were sent to the Isolation Hospital, Chicago, eight cases of smallpox during the last week. Two of the patients were colored men, and one was a woman, sixty years old, who claimed to have been vaccinated in childhood, and had an imperfect scar. She had, however, never been revaccinated and none of the other had ever been vaccinated

Tuberculosis in Cincinnati.—D. B. F. Lyle, superintendent and visiting physician to the Cincinnati Branch Hospital for Consumptives, had a consultation this week with Health Officer Clark W. Davis over the advisability of taking a census of the city to locate the places where this disease is most prevalent, with the idea of determining the cause for it and of establishing clinics in these sections for the treatment of the disease.

Completion of the McAllister Hospital.—The new McAllister Hospital, erected at Waukegan through the generosity of the late Mrs. J. McAllister, at a cost of $21,000, was opened for public inspection August 5. The building contains forty-five rooms.

The German Medical Temperance Association will hold its ninth annual meeting at Breslau on September 21, during the week of sessions of the Congress of German Naturalists and Physicians.

Obituary Notes.—Dr. Henry Bruce McCarroll died of pneumonia at his home in Morristown, N. J., on August 16, at the age of forty-seven years. He was born in Morristown and was graduated in medicine from the Medical Department of Columbia University in 1881. He practised for some years in this city, and was at one time instructor in medicine at the Post-Graduate School. He was a member of the New Jersey State Medical Society, and was visiting surgeon to the Memorial and to All Soul's hospitals.

Dr. Frederick Josiah Nott, one of the best-known homœopathic practitioners in this city, died recently in the General Hospital, Portland, Me., where he was taken after having become unconscious while on a train on the way to Bar Harbor. He had been ill for some months. He was fifty-two years old, and was a graduate of the New York Homœopathic Medical College in 1877.

Dr. George T. Heston died at Newtown, Pa., on August 16, at the age of seventy-eight years. He was a graduate of Haverford College, and of the Medical Department of the University of Pennsylvania in the class of 1852. He claimed to be a descendant of Llewellyn, King of Wales. His father came to America in 1784 and purchased that part of Philadelphia now known as Hestonville.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ECHOES FROM OXFORD—WEATHER AND AMUSEMENTS—CONVERSAZIONE—PATHOLOGICAL MUSEUM—DEMONSTRATIONS—EXHIBITION OF DRUGS AND APPLIANCES—MILK SUPPLY—ITEMS—PERSONAL—THERAPEUTICAL SOCIETY—OBITUARY.

LONDON, August 5, 1904.

THE British Medical Association was able to secure the co-operation of the magnates of the University, city and county of Oxford, but failed to obtain the favor of the clerk of the weather. Consequently, though the meeting is pronounced a success so far as scientific work and pleasant meetings go, the outdoor entertainments and excursions were practically spoiled. The Oxford meeting will be remembered as the rainy one. In London we had unsettled and showery weather, but the rain was an agreeable change in the midst of the most delightful summer we have had for many a year. But at Oxford our friends assure us it was very different. On Monday a thunderstorm began the change and the rain continued all night—a poor welcome for the early arrivals. Those who appeared later were scarcely less fortunate, and some hastened away as soon as the particular discussion in which they were interested had taken place. A few who went from one section to another were caught in the heavy showers, but nothing, I am assured, daunted the really zealous members. Some tell me they cared only for work and therefore weather did not trouble them, but others who anticipated the delights of the garden parties and other amusements confess to grievous disappointment. It was particularly unfortunate for the ladies who accompanied members, for what promised to be a most enjoyable picnic in one of the most delightful cities.

The weather could not spoil the *conversazione* at the museum, so there many took refuge from the heavy rains. It was given by the Vice-Chancellor and members of the University and proved a great success, at one time the crush was almost unpleasant, but as the guests found their way to the separate rooms where exhibitions and lantern demonstrations were given there was more breathing space. In the anatomy lecture room recent researches respecting cancer were demonstrated. In another room Mr. Sanger-Shepherd explained his method of color photography and showed his latest results. In another, numbers of the *Cunarder Bulletin*, printed in the mid-Atlantic from Marconi's wireless despatches, attracted some attention, but many more, especially ladies occupied the time in watching the antics of some performing mice. These were bred by crossing Japanese waltzing mice with ordinary albinos and illustrate the failure of Mendel's laws as to color inheritance.

The Pathological Museum is generally pronounced a success. The exhibits comprised macro- and microscopic specimens; drawings, plain and colored; stereoscopic photos; photos in color; photographic and other appliances; radiographs; instruments, old and new, and all sorts of apparatus for use in diagnosis or research. Many specimens shown being on important questions in the medical sciences and other illustrated papers read in the various sections. On Thursday afternoon Prof. A. E. Wright gave a demonstration of the methods of blood diagnosis, and Dr. R. N. Salaman another on the reservoir actions of the liver in cardiac disease.

The annual exhibition of drugs, instruments, sanitary and hospital appliances was so located that visitors could not help coming across it. It was rather more largely attended than usual. There is, of course, a very large commercial element in this annual show, but many practitioners seem pleased to look over it and examine any novelties presented. It was, however, I am informed, almost swamped by foods, beverages, and other objects often exhibited before, mineral water bottles occupying much space. The infants and invalid foods also made a great show, and one firm exhibited as a centerpiece a stuffed bull around which its meat preparations were grouped.

The milk supply was discussed in the State Medicine Section, Dr. Newman opening with a vigorous denunciation of existing arrangements. He said it was thought that tuberculosis was only conveyed when the udder of the cows was affected. But 20 per cent of the cows suffered from that disease, but in only 2 per cent. was the udder affected. He held that 32,000,000 of the supply were open to grave suspicion. The point is to meet the difficulty of the time between the milking of the cows and the consumption of the milk. But, further, he said the sheds, the cows, and the milkers are dirty, the retail dealers take no care to keep the milk clean and the consumers often take it in dirty jugs and still oftener neglect to keep it free from dust and dirt. Dr. C. Drysdale said the large firms conducted the business on sanitary principles. He thought tuberculosis very rarely conveyed in milk, though typhoid fever often was, but that was because the water used for washing the cans had been infected. One speaker said the cow was the dirtiest animal on earth. Another described the cans and other things as dirty beyond conception. Others agreed that the conditions called loudly for drastic changes.

Some comment was made on the fact that the lady doctors did not remove their mortar-boards at the cathedral service. This was perhaps to be expected, but the *Pall Mall Gazette* suggests it was because they were fixed with hat pins.

Great regret is expressed that Dr. Roddick was unable, on account of illness in his family, to attend and receive the honorary degree proposed to be conferred on him.

Dr. Osler, however, was present and was as heartily received as he always is, and, as a Canadian by birth, may be said to have represented the Dominion as well as Johns Hopkins. About 1,500 members attended the meeting.

Sir W. MacGregor, M.D., has been appointed Governor of Newfoundland by the King.

Mr. C. T. Dent of St. George's Hospital, succeeds the late Mr. Mackellar as chief surgeon to the Metropolitan Police force.

The testimonial to Mr. Alfred Willett is to be a silver medal attached to the Brackenbury Surgical Scholarship of St. Bartholomew's Hospital. Mr. Willett is to have a gold medal of the same design.

The Fellows of the Therapeutical Society have had a pleasant meeting in the gardens of the Royal Botanical Society.

Dr. Joseph Cranny of Dublin died on the 27th ult., aged fifty-nine. He was F.R.C.S.I., 1870; M.D., T.C.D., 1872; surgeon to Jervis Street Hospital, assistant physician at the Rotunda, and examiner at his college.

The death is also reported of Dr. Bannister, M.O.H. to Havant District Council, in his eighty-third year.

OUR PARIS LETTER.

(From Our Special Correspondent.)

X-RAY TREATMENT OF CARCINOMA—OXYGEN IN CHLOROFORM ANÆSTHESIA—DIAGNOSIS IN DIPHTHERIA—MEMORIAL TO PASTEUR—MEMORIAL TO PANAS.

PARIS, July 25, 1904.

AT a recent meeting of the Académie de Médecine, there were presented some interesting cases of carcinoma which had been treated by *x*-rays, and which showed radiotherapy to be a valuable resource. Monod, for instance, presented a woman fifty-three years old, with a cutaneous epithelioma of the temporofrontal region, which had first appeared ten years previously, had been ulcerated for a year, and, during that time, had made very rapid progress. The tumor, larger than a five franc piece, was diagnosed as a pavement-celled epithelioma, after histological examination of a portion removed from the ulcerated area. Surgical interference in this case, if it had been attempted, would have been difficult, and would, perhaps, have necessitated a partial resection of the bone to an unknown depth. Under these conditions, after repeated treatments of short duration and slight intensity, the tumor soon showed a decided diminution and rapid improvement. At the end of three months, a definite cure was obtained. Similarly, Imbert of Montpellier, to show that treatment by *x*-rays is efficacious not only in superficial cancerous tumors, but also in those deeply situated, cited a case of diffuse pelvic carcinoma, acute in course, cured by radiotherapy. It occurred in an old man, a diabetic, whose prostate gland was very large, and its limits impossible to determine. After eighteen treatments, of twelve minutes each, the prostatic tumefaction had entirely disappeared, so that one could, with difficulty, palpate the prostate, so small had it become.

At the Société de Chirurgie, Kirmisson and Delbet laid emphasis on the good results obtained in chloroform anæsthesia with the apparatus of Roth, Draeger, and Gugliminetti. This apparatus, by a very simple mechanism, makes possible the exact regulation of the quantity of chloroform mixed with oxygen which the patient inhales in the course of an operation. The advantages observed are the absence of the period of excitement, absence of vomiting, regularity of respiration and pulse, and tranquil sleep without interruption throughout the course of the anæsthesia.

Jalaguier was convinced of the great safety which this apparatus secures, by a case in which operation was necessary, on a girl six years old, in whom interventricular communication had been diagnosed. For this child, who became cyanosed on the least excitement, chloroform anæsthesia appeared to be full of dangers. But, thanks to the apparatus in question, it was accomplished without the least untoward incident.

At a meeting of Société des Internes et des Anciens In-

ternes des Hôpitaux de Paris, Martin gave a very interesting report on diagnostic measures in diphtheria. Clinical signs should, in his opinion, have the first place in the diagnosis of diphtheria. It is true that the bacteriological diagnosis is certain, but it is useless to lose time by making it; surely it is better to give subcutaneous injections of antidiphtheritic serum, otherwise one will lose precious time. Bacteriological diagnosis should come, then, after the treatment. And it should be well done. The serum used should be perfectly clear; the spatula designed for coming in contact with the false membrane, should not be contaminated by touching the lips, gums, teeth, etc. The colonies should grow in eighteen to twenty-four hours. Under the microscope, both long and short bacilli may be seen. It has been thought that the latter were only pseudo-diphtheritic bacilli, but in reality no one point by which differentiation has been claimed is characteristic. There is but little difference, and the short pseudo-diphtheritic bacilli are only attenuated diphtheria bacilli.

On July 16 the President of the Republic met with the presidents of the Chamber of the Senate, on the Place de Breteul in Paris, to dedicate a monument to the illustrious, and never to be forgotten, Pasteur. Foreign scholars of all countries were represented by many delegations at this ceremony. The principal addresses were made by the Ministre de l'Instruction Publique, by Gaston Boissier of the Académie Française, and by Professor Grancher. The last mentioned had had the good fortune to live for ten years under the influence of the great scholar. He had known him in his happy days and in his hard days; and he proceeded, for the sake of the young men dreaming of glory, to tell briefly what so great a reputation had cost its winner.

With the Ministre de l'Instruction Publique presiding, a monument was also dedicated recently, to Professor Panas, the celebrated ophthalmologist who died last year. This monument, erected by the friends, the followers, the pupils of the founder of the ophthalmological clinic of the Hôtel Dieu, is designed to perpetuate the memory of the master in this clinic where he consecrated many hours each day to the care of patients and to the instruction of students.

A NEW MEDICAL TEMPERANCE ORGANIZATION.

To the Editor of the Medical Record:

Sir: The American Medical Society for the Study of Alcohol and Other Narcotics was organized June 8, 1904, by the union of the American Association for the Study of Inebriety and the Medical Temperance Association. Both of these societies are composed of physicians interested in the study and treatment of inebriety, and the physiological nature and action of alcohol and narcotics in health and disease. The first society was organized in 1870, and has published five volumes of transactions, and twenty-seven yearly volumes of the *Quarterly Journal of Inebriety*, the organ of its association. The second society began in 1891, and has issued three volumes of transactions, and for seven years published a Quarterly Bulletin containing the papers read at its meetings. The special object of the union of the two societies is to create greater interest among physicians in the study of one of the greatest evils of modern times. Its plan of work is to encourage and promote more exact scientific studies of the nature and effects of alcohol in health and disease, particularly of its etiological, physiological, and therapeutic relations. Second, to secure more accurate investigations of the diseases associated or following from the use of alcohol and narcotics. Third, to correct the present empirical treatment of these diseases by secret drugs and so-called specifics, and to secure legislation prohibiting the sale of nostrums claiming to be absolute cures containing dangerous poisons.

Fourth, to encourage special legislation for the care, control, and medical treatment of spirit and drug takers. The alcoholic problem and the diseases which center and spring from it are becoming more prominent, and its medical and hygienic importance have assumed such proportions that physicians everywhere are called on for advice and counsel. Public sentiment is turning to medical men for authoritative facts and conclusions to enable them to realize the causes, means of prevention, and cure of this evil. This new society comes to meet this want by enlisting medical men as members and stimulating new studies and researches from a broader and more scientific point of view. As a medical and hygienic topic the alcoholic problem has an intense personal interest, not only to every physician, but to the public generally in every town and city in the country. This interest demands concentrated efforts through the medium of a society to clear away the present confusion, educate public sentiment, and make medical men the final authority in the consideration of the remedial measures for cure and prevention. For this purpose a most urgent appeal is made to all physicians to assist in making this society the medium and authority for the scientific study of the subject. As secretary, I shall be pleased to give any further information.

Mind Cure from the Standpoint of the General Practitioner.—Robert T. Edes considers it certain that there are many disease processes over which the mind can have no control. Such are pyrexia, anæmia, etc. Over many processes of nutrition, too, it can have little influence. Over infections, degenerations, slow organic processes, such as control the duration of life, the general health and vigor of the constitution, psychic influence is practically nil. Psychic influences come in contact with organic processes only through the nervous system, especially by vasomotor and secretory nerves, and motor and sensory ones as well. The secretions of digestion are largely affected by the nerves; so are the functions of the bowels; hence, these are amenable to psychic influences. The functions of the kidneys and skin may, perhaps, be also so influenced. The intimate relations between the genital functions and mental and moral conditions are well known. So with the cardiac functions. In diseases that we call functional, the psychic influence has its greatest field. Still, in many forms of insanity, notably melancholia, it cannot act. In cases in which symptoms counterfeit organic disorders, the mental healer finds his field. In neurasthenia, in which there is little real loss of nerve power, mental influences are of use; if there is real loss of nerve power this must be regenerated through other means. Hysteria is the peculiar stamping ground of the mental healer. As to the methods of using mental healing, they are various. Suggestion may be made use of without hypnotism. The strenuous repetition of a positive assertion undoubtedly produces an effect. Many of the modern mechanical means of treatment do much of their work by mental effect, such as electricity, and various kinds of movements. As an adjuvent to the healing forces of nature and time, psychical influence will always be a precious resource to the physician.

A Consideration of Mental Therapeutics as Employed by Special Students of the Subject.—James J. Putnam tells us that some sort of specialized mental influence or education is often needed in cases of neurasthenia, aside from the improvement of nutrition. Another class of cases that may be benefited is that in which may be placed sufferers from morbid fears or occasional outbreaks of a hysterical nature. The problem is that of inducing in such patients the sentiments of courage, confidence, patience, and determination, and making them familiar with the dangers that are likely to threaten from without and within. In the class of diseases represented by morbid fears, fright psychoses, insistent ideas, and epileptiform or hysterical outbreaks, some of the best work has been done. A series of graduated efforts or one strong effort, in which the patient is supported by the physician, may overcome a morbid fear of long standing. Or such a fear may disappear before a determined attempt to go over and remember all the details of its first occurrence when it turns out to be not so dreadful after all. It has been found that painful experiences work mischief just because they are hidden from the patient's view. The hidden experience should be brought out into the clear light of consciousness. Hypnotism may be of great use here. It has been learned that it is erroneous to think that hypnotism tends to loss of independence and weakening of the will. In cases of traumatic hysteria, we have examples of typically painful and insistent experiences occurring in persons not of hysterical temperament. They are peculiarly amenable to mental therapeutics. General and local treatment is also indicated along with the mental treatment. No attempt need be made to draw a sharp line between physical and mental therapeutics. A kinship exists between the influence that improves the nutrition of the brain by increasing the harmony and efficiency of its functions, and that which reaches the same end by improving the quality of its nutrient fluids, or the mode of their distribution.

Journal of the American Medical Association, Aug. 20, 1904.

Ascaris Texana; a Note on the Hitherto Undescribed Ascaris Parasitic in the Human Intestine.—Allen J. Smith and Richard A. Goeth present a communication based on two female specimens of an ascaris. Together with a number of other examples supposed to be of the same kind, they were passed in the intestinal discharge from an adult

white man, the patient stating that for several years he had passed similar parasites from his bowel. The patient complained of his inability of ridding himself of the pests, which, however, gave him no particular inconvenience. Efforts to obtain other specimens since last year, when these were passed, have not been successful, and the absence of a male example renders the establishment of a full specific description impossible for the present. The two specimens were mounted, unstained, in balsam, on glass slides; and, from the influence of the reagents used in the balsam-mounting medium, as well as from compression and division of each specimen into three lengths for convenience of mounting, were not in favorable state for detection and clear recognition of many of the finer details needed in the study. Sufficient data may, however, be determined from material in hand to surely differentiate the worm from the known ascarides of the human intestine, and to make the idea of its identification with other known members of the genus improbable. They hesitate to insist on the absolute correctness of the view of the novelty of the species until the description given by them may be verified by study of fresh material and male specimens; but they feel from the data in hand the specimens presented may at least be tentatively accepted as constituting a new species, and would suggest that it be known as *Ascaris texana*. From its general appearance it is most closely allied to ascarides known to be parasitic in certain birds and reptiles.

Static Foot Error; Analysis of One Thousand Cases.—William E. Blodgett contributes this article. The female cases were in moderate excess. Two-thirds of the cases were under forty years of age. Predisposing or contributing to the weight-bearing error were long, slender feet, hallux valgus, mild, fleeting polyarthritic symptoms, probably toxæmic, and depression of physical vigor, without local symptoms, except in feet. The commonest direct cause was trauma. In slightly less than half the cases the duration of symptoms at entrance was six months or less. In about two-thirds of the cases both feet gave symptoms. In slightly more than 95 per cent. of the cases pain was the leading symptom, and in about two-thirds of these cases the pain was in the ankle, and foot only, most frequently being referred to the astragalo-scaphoid joint. The commonest location of pain when above the ankle was in the calf. In nearly all the cases the anterior arch was involved; in 156 cases, notably spread and flattened; and in 116 cases, painful. The degree of deformity was no indication of the severity of the symptoms. Of 77 cases of marked hallux valgus, 14 suffered from broken anterior arches, while in the 1000 cases the percentage of broken anterior arches was only 6.8 per cent. In the great majority of the cases (86.7 per cent.) a steel sole plate was advised. The prevailing type of plate was the square one, supporting nearly the whole width of the sole. Flannel bandages and supporting adhesive strapping were employed when indicated. Local and general tonic treatment, foot exercises, right shoeing and correct muscular standing and walking were often ecommended. Rigid valgus was treated by adhesive strapping in as much correction as possible, followed by a plate when the foot became sufficiently flexible; intractable cases were forcibly corrected by manipulation under ether, and retained overcorrected by plaster cast, followed by plate, and usually Thomas sole. Thomas heels, or heel and soles, were occasionally used in promising cases in substitution for plates. Of the 1000 cases 513 did not return for continued treatment. In two-thirds of the plate cases the plates were raised, usually within a month. The results of initial treatment show entire relief in 27.6 per cent., relief in 43 4 per cent., slight relief in 5.3 per cent., and no relief in 23.7 per cent. The results of the plate treatment of static error affecting principally the longitudinal arch show entire relief in 32.7 per cent., relief in 44.9 per cent., slight relief in 7.8 per cent. no relief in 13.6 per cent., and condition made worse in 1 0 per cent. When the anterior arch was involved entire relief followed in 32.1 per cent., relief in 53.6 per cent., and no relief in 14.3 per cent. The results of treatment by Thomas soles without plates showed that it was less effective than plate treatment. In three-quarters of cases with restriction of inversion sufficient to require corrective adhesive strapping, the pain was entirely or much relieved. In two-thirds of the cases of forcible correction under ether the valgus nd rigidity returned. Among the 350 plate cases in which results are known, only 15 removed their plates with relief. In 95.7 per cent. of all the plate cases the patients continued to wear their plates.

Practical Notes on Ointments, Their Use and Abuse.—L. Duncan Bulkley considers this topic under the following headings: (1) Basis for ointments. The first requisite is that it shall not be irritating and shall be of a proper consistency, and the tendency to become rancid should never be forgotten. Lard is a common base, and it is usually treated with about 2 per cent. benzoin to prevent rancidity. Wax and oils tend to rancidity. The petroleum products are much used, but vaselin is not acceptable to every skin. Vaselin and albolene are of value when it is desired to have a lubricant, or a soft ointment to penetrate, but this will not answer as a protective ointment. Lanolin is rarely suitable as a basis alone. Glyceride of starch is often good as an excipient in irritable conditions. Mutton tallow melted and incorporated with oil makes an excellent inunction for dry, harsh skins. The most serviceable base for most ointments is cold cream. (2) Ingredients of ointments. The addition of carbolic acid, ichthyol, or oil of cade is of great value as an antipruritic. Salicylic acid promotes the growth of healthy epithelium. Wilkinson's ointment for scabies may be further improved by the addition of tar ointment and liquid storax. (3) Compounding of ointments. The directions in the Dispensatory are very clear, but not always followed strictly. The most common error in their preparation is in having gritty particles, so irritating to the skin surface. All mineral ingredients should be thoroughly triturated in a mortar, with a few drops of oil, so as to make a fine paste. (4) Strength of ointments. It is well to begin with mild applications, increasing the strength as indications occur. (5) Properties of ointments. Ointments are required for many purposes, and their action may be lubricating, protective, soothing, astringent, absorbent, stimulating, or antiparasitic. All of them may prove healing according to the nature of the complaint and the condition of the skin. (6) Mode of application. When an ointment is used for lubricating it should be taken on the palms and the body should be freely anointed, with friction, morning and night, until much of the ointment has been absorbed. If there is a raw, eczematous surface the ointment should be spread on the woolly side of lint and firmly bound to the part. In parasitic diseases of the scalp it is often wise to apply the ointment with a stiff stencil brush, with considerable friction. In old eczematous patches benefit is derived often from friction with the fingers. In general itchy conditions it may be necessary to make applications many times day and night. It is rarely advisable to wash the surface which are at all raw, but the necessary cleansing may be done by gently wiping them with absorbent cotton. (7) Indications and contraindications for the use of ointments. In some acute inflammatory conditions of the skin lotions and powders suit far better than ointments, while in the most chronic conditions, with dry, rough skins, ointments are called for. A single patch of chronic eruption will require much stronger applications than an acute or generalized eruption. The almost general use of zinc ointment is explained largely by its relative harmlessness.

Medical News, August 20, 1904.

Technical Errors in the Use of Rubber Gloves.—Howard D. Collins thinks that the rubber gloves are often rendered useless by the manner in which the glove is put on: the left glove is worked in by means of the right hand, which is presumably not absolutely sterile, otherwise the gloves would not be used; or the glove is drawn on under water, the water having been contaminated by the hands previously. Again the excess of liquid dripping from the wrist of the glove into the wound may contaminate it, or a broken finger tip may have the same effect. The preparation of the glove is careless; it should be picked from the sterilizer with forceps and handed hot and wet to the surgeon. The author sterilizes gloves by boiling them, turned inside out; he then dusts them with sterile starch or lycopodium, turns them by means of sterile forceps, and places them between folds of sterile towels. The gloves are put on by using sterile gauze to take hold with. The hands do not touch them at all.

Autointoxication of Gastrointestinal Origin.—Clifton Mayfield sums up the causes of autointoxication thus: it may result from ingestion of decomposing food; from fermentation and decomposition of food in the alimentary tract; or from reabsorption of bile or fecal matter. The gastrointestinal changes are the result of chemical processes and bacterial activity, producing sulphuretted hydrogen, potassium and ammonium, organic toxins and ptomains that are absorbed into the circulation. If the kidneys are incompetent or over-worked, and the liver is incapable of eliminating the poisonous products, absorption takes place and symptoms of poisoning occur. The acute toxæmia of decomposing meats and such articles is less serious than the chronic intoxications; such occur in cancer of the stomach, chronic dyspepsias, chronic diarrhœa, and dilatation of the stomach. Intoxication may occur in personal idiosyncrasies against certain articles of food. Constipation may originate it Many cases of insanity depend upon toxins affecting the brain cells, disordering their metabolism or even destroying them. The treatment consists in avoidance of the introduction of

foods liable to fermentation; the lessening of bacterial energy in the gastrointestinal tract, in which lavage, colon-flushing, and laxatives play an important part; and relief of the system from the poisons by aiding in their excretion by the usual organs of elimination.

Recognition and Management of Beginning General Paresis.—Charles Lewis Allen states that the diagnosis of general paresis cannot be made on any one symptom; but severe neurasthenic or hypochondriacal symptoms, or any marked mental change without known cause, in a man of fifty years is suspicious. If there was previous syphilis the probability of paresis is great. If there is also immobility of the pupils, loss of knee-jerk, while there are characteristic speech disturbances, and a convulsive seizure, there is no longer any doubt. Syphilis, the abuse of alcohol, the struggle for existence, are chiefly responsible for general paresis. It may occur at any age, but is especially a disease of fifty or thereabouts. The disease begins slowly with some form of mental change. There are three general types: (1) The dement type, characterized by mental failure. (2) The classical type, with grandiose feelings. (3) The melancholic type, characterized by depression, sleeplessness and hypochondriacal ideas. Delusions are never logical; hallucinations are rare; the knee-jerks are altered, lost or exaggerated; there is Argyll-Robertson pupil; sometimes there is optic atrophy; there is imperfect coördination, shown by tremor, and inability to perform fine movements of the hands, such as writing; there is change in speech, inability to pronounce complex words; there is loss of memory; finally there may be paretic seizures, epileptiform, apoplectic, or simply of vertigo and slight muscular twitching. The treatment can be only palliative; to sustain the vital forces and prevent excitement; to protect the public and the family from the foolish and unjustifiable acts of the patient are the main objects. The best place, in most cases, for the patient is in a sanatorium.

The Biological Interpretation of Cancer.—Alexander Spingarn seeks in the phenomena of evolution the solution of the question why cancer occurs. He reminds us that even if we find the parasite of cancer, this will be only the exciting, not the efficient, cause of the disease. Heredity and variation, including natural selection, are two important factors in evolution. The real explanation of cancer should be sought in the laws that govern the growth and multiplication of cells. The law of growth has been firmly established. The nutrition of the cell depends upon its capacity to absorb. When the cell becomes incapable of absorbing sufficient nutriment cell-division occurs. The law of evolution has determined the absolute size of every organ; there is a fine adjustment of tissue to tissue, organ to organ. Each tissue depends for its health upon the chemical equilibrium of its immediate environment. A tissue which has acquired excessive proportions will undergo necrosis or degeneration. In the organic community overgrowth of any kind is as disastrous as deficient growth. Natural selection will account for the limitation of size of the different organs, perpetuated by heredity. The vital mechanism changes its size and power according to the demands made upon it. In this adaptive capacity of the individual tissues is the secret of pathological hyperplasia. In exuberant callus, in cheloid, in the excessive increase of red blood cells are instances of extravagant and riotous regeneration of tissues as the result of abnormal stimuli. The tissues are endowed with a capacity to grow which has been stilled by the needs of the organism. This capacity may be awakened by anything which tends to embarrass or limit the activity of the particular part. A sort or atavistic reversion to the hereditary habits of the cell, when self-multiplication was the most prominent phenomenon of cellular activity, as a result of abnormal stimuli, may account for the proliferation of cells in new growths. An unusual stimulus, as of injury of an organ, may excite the bodily cells to assume the habits of their primitive ancestors. A jagged tooth, a long-continued ulceration, chemical poisons may act as such stimuli.

New York Medical Journal, August 20, 1904.

The Management of Genital Sores.—E. Wood Ruggles says that there is no other class of cases so frequently neglected and mismanaged as that of venereal diseases, and states that the only safe course to pursue in the management of genital sores is to regard them with all suspicion and, in fact, to hold them all as syphilitic until proven otherwise. Again he believes it to be equally important to refrain from instituting general specific treatment until the diagnosis of syphilis is confirmed by the secondary symptoms. The venereal trinity, an indurated ulcer, multiple, shotty, enlarged glands in the groins, and a roseola ensuing in from five to ten weeks after the first appearance of the ulcer, are the three requisites to the earliest possible certain diagnosis of syphilis. The most reliable single sign of syphilis is the roseola. The simpler the treatment of genital sores the better. One cardinal principle is to cauterize no such sore with silver nitrate or other caustic that produces induration, until all doubt about the diagnosis is removed. A soft chancre is cauterized thoroughly with carbolic acid and then some antiseptic drying powder is applied. In the treatment of herpes, cleanliness and dryness are the most important factors. Frequent washings with some mild antiseptic and the application of salicylic acid in starch, 1 to 100, on a thin layer of cotton, will quickly cure. In the treatment of the hard chancre it matters little what line of local treatment is used, tepid water being as good a dressing as anything.

The Finsen Light Treatment.—Rollin H. Stevens says there is much misunderstanding as to the true nature of the genuine Finsen light, and as to what it will accomplish. Reports of Finsen light treatment given with apparatus of other construction all lack the features necessary to secure the most marvellous cures which are reported from Finsen institute, Copenhagen. It is frequenty asserted that the efficient agent of the Finsen light is the ultraviolet ray. Dr. Bie has shown that the blue and violet rays penetrate deeply into the skin, but only when it has been made bloodless, and the ultraviolet rays can, under no circumstances, penetrate deeper than the superficial layer of the skin, but they give rise to dilatation of the blood-vessels, which may persist for months. The writer quotes experiments because he desires, in fairness and justice to the Finsen treatment, to protest against the common practice of denominating as Finsen lamps any kind of a phototherapeutic lamp, the construction of which may involve only few or none of the principles enunciated by Finsen. After a year's experience with the Finsen light and several weeks' experience in the Finsen Institute, and other places, he believes that in superficial skin diseases which are suitable for the Finsen treatment there is no more effective and speedily curative agent known to the medical profession.

Renal Insufficiency.—Antonio M. Crispin believes that all prolonged gastrointestinal inflammations will react on the liver, and this gland is one in which the most urea is formed. The diminution of the quantity of urea in all hepatic diseases is of very grave omen, and the daily examination of the urine enables us to tell whether the disease is stationary or progressing. The kidney, in affections of the liver, is like a barometer, by means of which we can prognosticate the outcome, and acts as a safety valve, and upon its permeability depends the future of the patient. As the proportion of solids in the normal urine bears a certain ratio to the normal body weight, below a certain percentage of which they cannot fall without indicating "renal insufficiency," tables were prepared giving the total urinary solids for certain weights. By obtaining the amount of solids passed by the patient and comparing with the tables given it can readily be ascertained whether this was above or below the normal amount. This applies to urine free from sugar and albumin. Water is the best diuretic and is indicated when the solids are normal but the urinary water is diminished. When there is a deficiency of the solids, this may be increased by fractional doses of calomel. Sodium salicylate will increase the amount of solids eliminated, as it increases the functional activity of the liver; but it must not be given if the kidneys are structurally changed. When the amount of solids is excessive, and when there is no contraindication, such as diabetes, zinc valerianate, in grain doses, has given good results in checking this waste, especially when dependent upon an over-active liver.

American Medicine, August 20, 1904.

The Prognostic Importance of Meteorism in Pneumonia.—Heliodor Schiller states that in most cases of pneumonia pneumococci may be found in the peritoneum and in the blood. The cocci seem to pass through the diaphragm, in all layers of which they have been found, and to infect the peritoneum. They may also pass to the peritoneum by way of the lymphatics. In these cases meteorism is marked. The presence of streptococci may also be of importance. From the observation of a number of cases of pneumonia the author gives us the following conclusions: (1) Meteorism often accompanies pneumonia; (2) in lighter degrees it may be produced by deficiency of mechanical action of the diaphragm; (3) as a pronounced condition it is rare; (4) when very marked it is one of the worst prognostic symptoms, as it may point to a complicating peritonitis.

Myelitic Symptoms Occurring during the Puerperium.—Alfred Gordon draws attention to the necessity of not ignoring symptoms such as pain, paraplegia, etc., after labor, while classing them indefinitely as nervous symptoms. The absence of cleanliness and aseptic precautions at delivery may cause unexpected complications. A purulent discharge from the uterus should lead us to make immediate search for its cause. A transient and

curable inflammation of the central nervous system and the occurrence of myelitic symptoms are possible from lack of asepsis. He describes two cases in which there had been carelessness in the application of forceps, and in which a purulent discharge had existed for some time before causing the physician to search for the source. In one patient there was an abscess behind the vagina which had infected the spinal cord. Symptoms of myelitis supervened, paraplegia, rigidity, increased tendon reflexes, ankle clonus, marked sensory and bladder and rectal disturbances. After instituting aseptic measures and drainage, all the symptoms disappeared and the patient entirely recovered.

A Plea for More Just Judgment of Narcotic Drug Users.—George E. Pettey states that morphine *habitués* are unjustly judged to be moral perverts and entirely unreliable persons, because they may be forced in self-defense to resort to unjustifiable means to obtain the drug which has become a physical necessity to them. The sudden deprivation of the drug may cause intolerable suffering, violent delirium, transient or permanent dementia, or even death. In any case it causes heart weakness, often uncontrollable diarrhœa, and such a condition of misery that the patient is unable to bear his sufferings. Self-preservation is a law of nature, one of the strongest, and no man can be blamed for using whatever means he finds necessary to that end If the public and physicians would recognize that it is unjustifiable to deprive the morphine user suddenly of his drug, that he is physically unable to stop it suddenly, the patient would be in a better position for cure The author cites cases that have been treated by him, of persons of good moral character, business ability, and standing in the community who have for years used the drug, and have manifested no symptoms of moral degeneration or perversion. These were cases in which the habit was acquired during sickness, and in which the relatives recognized the necessity of the drug to the patient, and supplied it as needed. There was no incentive to deceit or crime, and no tendency in that direction was manifested. These patients were cured by appropriate treatment after having used the drug for years. The cure requires gradual deprivation, and the most careful handling and supportive treatment to bring the case to a successful issue. Such persons should be treated as subjects of misfortune and serious disease, rather than frowned upon as "morphine fiends."

British Medical Journal August 13, 1904.

Malta Fever.—A. F. Bradshaw asserts that the so-called Malta fever is one of the most tedious and refractory of diseases often lasting for years, and being peculiarly subject to relapses. It is caused by the micrococcus melitensis, a germ of very minute size and which grows very slowly on artificial media. Of its habitat outside of the body, very little is known. Cultures kept at 22° retain vitality for fourteen months; it lives in milk for three weeks, in water for three days; in sea-water it dies almost immediately, while in urine it lives five or six days. In a dried condition it retains vitality a much longer time; in dust for sixty-nine days, on dry fabrics longer It has never been found in the dust of streets. It grows very slowly at ordinary temperatures, best at blood heat; exposure to the sun kills it quickly. Of its mode of entrance we are ignorant. It is produced easily by inoculation, the disease occurring in the inoculated animal in a typical form. There have been many accidental inoculations in the laboratory. It is thought possible that the disease may be carried from one to another by means of mosquitos. It is found in very small numbers in the blood, and colonies have been found in the urine, so that this may be the means of carriage. It is not found in the sputum, the expired air, the sweat, or the intestinal contents.

The Influence of Antenatal Conditions on Infantile Mortality.—G. F. McCleary considers that the whole subject of infantile mortality stands much in need of a more searching analysis. Prochownik had brought forward evidence to show that the development of the fœtus is definitely affected by the diet and mode of life of the mother during pregnancy. By dieting anæmic or fat and weak women, a more normal pregnancy and puerperium have been secured. The size of the fœtal head has been modified, and rendered more compressible in cases of pelvic contraction by diet. Defective antenatal nutrition causes the infants of the poor to start out in life at a low level, and they easily succumb to hardships. The influence of alcohol as used by the mother has an important effect on the child. The alcohol enters the child's veins directly from those of the mother and exerts its injurious effects. Antenatal conditions cause many of the deaths from marasmus, atrophy, debility, inanition, and convulsions. At the same time, they cause the child to have less resistance to the ordinary children's diseases and diarrhœal troubles Premature birth, atalectasis, cyanosis, and congenital effects definitely depend upon antenatal causes. There has a been relative increase in the number of premature births in the last two decades. Artificial means of preventing conception are more often used, and cause endometritis and other uterine diseases which favor premature birth. Our birth rate is decreasing, and it would appear that there is a diminution as well in the quality of our output of babies.

Caisson Disease.—Thomas Oliver says that experience has shown that when care is taken men can work at great depths under water and under enormous pressures with comparative safety for some hours at a stretch, if sufficient air is supplied and time allowed on emerging for decompression. As the caisson sinks the pressure increases; at a depth of 100 feet the pressure is 3 atmospheres, at 200 feet it is 6 atmospheres. As the lock descends the workman undergoes compression; as he emerges, decompression occurs. Under some circumstances noxious gases escape from the soil, and the lamps tend to vitiate the air At the same time, large quantities of air are constantly pumped into the cylinder, rendering the air more pure. When the men suffer, it is usually in consequence of too rapid decompression. At least six minutes should elapse during the decompression; if more is occupied the nervous men become worried. When the outer door is opened a thick fog escapes, and the atmosphere is icy cold. The physiological effects of compressed air are various; there is no mechanical effect on the circulation, no rise of pressure. The pulse and respiration may increase from nervousness, but this soon passes off There is no difficulty of breathing, and seldom faintness. There is buzzing and sometimes pain in the ears, due to the difference of pressure inside and outside of the drums. This is relieved by swallowing, which causes air to enter the eustachian tube. Experience has shown that, as greater depths are reached and higher pressures used, the dangers of injury become greater. Poisonous gases escaping from the bottom may have much to do with the injurious effects. During compression air enters the blood and causes frothing of the blood, bubbles may be seen escaping in the frog's foot. Beyond this, the nitrogen, which is increased in amount, is harmless. Oxygen in a high state of tension acts as a protoplasmic poison, depressing the bodily temperature, and producing convulsions and death in animals. It also brings about, rapidly, an acute inflammation of the lungs, acting simply as an irritant, without any bacterial action. Intense hyperæmia and hemorrhagic congestion can be produced in a very short time. The symptoms of caisson disease do not occur in the caisson, but after decompression, and the pains may be at once relieved by recompression in a medical lock. The men suffer chiefly from pains of a very severe nature, in the muscles and joints, due to the escape of air into the tissues. Gavaret thinks it due to the pushing asunder of small nerve fibers connected with capillaries that are distended with air, and the rupture of small blood-vessels. Giddiness and epistaxis may occur. Frequently there is loss of sensation in the legs, as well as loss of power, numbness and formication and retention of urine. The paraplegia may last for some months; reflexes are exaggerated and ulcers may form on the heels and soles of the feet. There may be loss of hearing or sight, delirium, unconsciousness, and loss of speech. Prevention of caisson disease consists in carefully selecting the men, rejecting all intemperate men, or those who have catarrhal troubles, lung, heart, or kidney disease. The caisson should be well ventilated, the decompression slow, the shifts short, and the temperature may be raised with advantage, especially after leaving the lock. The immediate treatment consists in recompression.

Deutsche medizinische Wochenschrift, August 4, 1904.

Trauma as an Etiological Factor in Aortic Insufficiency.—F. Sinnhuber describes two forms of violence which may bring about a rupture of the valves. The one is due to muscular exertion, the other to external violence in the form of a blow or crush on the thorax. In addition to these there is also a spontaneous rupture, which occurs during the course of a severe endocarditis when the arterial pressure is suddenly raised by fright or mental shock. Intermediate between these two are cases in which trauma is followed by endocarditis, in the course of which rupture of a valve may result. The latter, however, is almost impossible to diagnose clinically. The author reports three cases in which the rupture resulted from external violence, in the form of a fall on the thorax. The diagnosis could in no instance, however, be confirmed by autopsy, and was based on the signs of an aortic insufficiency coming on soon after injury of the kind described. The original paper should be referred to.

Mixed Infection with Typhoid and Paratyphoid Bacilli.—H. Conradi attempts to add further proof of the etiological unity of the disease, by relating a case in which the simultaneous invasion of both bacilli called forth the

clinical symptoms of typhoid fever In an eight-year-old girl there was noted irregular temperature, splenic tumor, roseola, slight intestinal disturbances. Culture tests made on the fifth day showed colonies of both forms of bacilli on the same agar plate. The author believes that the finding of the two types in the initial stages of the disease necessarily stamps the case as a mixed infection. In addition to this it was determined that the infection took place from contaminated ice which the patient had swallowed. The bacilli could readily be demonstrated in the latter, and also in the water supply from which it was produced.

The Treatment of Spastic Aphonia.—E. Barth discusses the therapy of this condition from a new point of view. The writer's idea is to avoid the extreme closure of the epiglottis by mechanical means. The contraction of the glottis, which interfered with tone production, could be prevented by introducing a wedge between the vocal cords. The mucous membrane was very sensitive in the case in which he tried it and thorough cocainization was necessary, before the wedge-shaped tip of a sound could be inserted between the anterior ends of the cords. Phonation after a few efforts was then possible, but the next morning aphonia was again present. In the belief that the excessive contraction of the glottis had an important influence, a larger wedge was inserted, so that even the approximation of the vocal processes was prevented. After a number of efforts by the patient, speech returned and lasted for several weeks, when the procedure was repeated with equally good results. In two other patients the results were immediately permanent.

Münchener medizinische Wochenschrift, August 2, 1904.

Unusual Injury to the Eye.—Noldeke reports a unique instance in which the sclera had been wounded by a whip-lash. This wound was cleaned and sutured, but after a time an abscess developed in the vitreous body, which finally necessitated enucleation of the eyeball. Subsequent examination of the latter disclosed the presence of a small knot of silk derived from the tip of the lash. The mechanics of the injury may be explained as follows: The sclera was undoubtedly cut by the extreme tip of the snapper of the whip; as the latter was withdrawn, the edges of the wound held fast to the snapper, which broke off because the silk was rotten, and the knot remained in the eye. This is the third case of the kind thus far reported.

The Etiology of Intestinal, Biliary, and Renal Colic.—Wilms questions the statement made by Nothnagel that intestinal colic consists of an irritation of the nerves in the walls of the gut, which is brought about by a marked tonic contraction of the intestinal tube, biliary, renal, and uterine colic being likewise produced by the spastic contraction of the smooth muscles. Wilms doubts this because it is a common observation of surgeons that the gut can be freely handled and sewed without producing any sense of pain. A pulling on the mesentery is, however, very painful, and this the writer considers to be the primary cause in producing the colic. In the presence of a stenosis, the distended intestinal loops above the constriction assume the form of folds. When a tonic muscular contraction sets in, the internal pressure, equally divided over the interior of the tube, would tend to cause the latter to assume a straight line, but this is prevented by the mesenteric attachments and the painful pull results. In the case of biliary colic, Wilms also believes that the pain is not due to distention or the passage of a stone through the ducts, but is produced by the pulling of the distended biliary passages at their point of attachment, where the sensory nerves become involved. This would account for attacks of biliary colic without the presence of gallstones. Renal colic may be readily explained in the same manner.

The Effect of Radium Rays on Animal Tissues.—H. Heineke has already reported on the histological changes which are produced by the Röntgen rays in the blood-forming organs—bone marrow, spleen, lymph follicles of the intestinal canal, lymph glands, thymus—comprising a destruction of all the lymphoid tissue in the body, a disintegration of the cells of the splenic pulp and the bone marrow, and finally an increase of the pigment in the spleen. His present contribution deals with the radium rays in a similar manner. Experiments in animals showed that the latter exerted the same effects on lymphoid tissue as the Röntgen rays, within a few hours a disintegration of the nuclei of the lymphocytes took place in all organs which were exposed to the radium rays. These changes occur in great part during the first twenty-four hours, but the cells of the splenic pulp are not affected during this time. It is apparent, therefore, that the radium rays, like the *x*-rays, can attack the lymphoid tissue through the unbroken skin. The sensitiveness of the lymphoid tissue to the radium salts is remarkable, an exposure of a few minutes resulting within a few hours of tissue changes of considerable extent. It seems reasonable to conclude from these experiments that the radium rays are accompanied by the same physiological action as those proceeding from the Röntgen tube, and the effects on living tissue are practically the same.

French and Italian Journals.

The Action of Carneous and Amylaceous Regimes on the Retention of Chlorides and Urea.—Achard and Paisseau states that the amylaceous régime, which is more easily borne and more easily varied, increases the volume of urine and sometimes admits of better elimination of the chlorides. A patient suffering with aortic insufficiency and œdema, on the amylaceous diet voided an average of 2430 gm. of urine daily, in contrast to 1380 gm., while on the carneous régime. The excretion of chlorides was 6.50 gm., during the period of the amylaceous régime, in contrast with 4.30 gm., during the carneous régime. In demonstrating the possible diminution of diuresis, and the imperfect elimination of chlorides and urea under the carneous régime, Archard and Paisseau have confirmed experimentally the results already obtained clinically.—*Journal des Praticiens*, July 30, 1904.

Neoplastic Stenosis of the Œsophagus.—A. Michelazzi has collected seven cases of neoplastic stenosis of the œsophagus, treated during seven years at the Medical Clinic of the University of Pisa. These were collected from among 1800 cases, which presented themselves during that time. The principal symptoms are dysphagia, concavity of the abdomen, pain, a tympanitic area above the stricture when dilatation has occurred, which disappears on drinking water, emaciation, and, in some cases, impairment of voice from pressure on the nerves in the chest. The commonest form of stricture of the œsophagus is the neoplastic, the carcinomatous. Ulceration may occur into the air passages late in the course of the disease. The symptoms of this condition are cough on swallowing anything, even water. The author finds cancer of the œsophagus to be rarer than the other forms of the disease. It occurs most often in the lower third of the œsophagus. It is found only after the age of fifty years. In all his cases there was found no assignable cause for the location of the disease. The duration is short, on account of the rapid failure of nutrition, from three to seven months, in the author's cases.—*Giornale Internazionale delle Scienze Mediche*, June 30, 1904.

Action of Corrosive Sublimate on the Kidneys.—Aldo Tartarini-Gallerani has studied the subject of calcareous degeneration of the kidneys after mercurial poisoning, and has experimented on rabbits by injections of sublimate directly into the cortex of the kidney, a method used only by himself. It has been long known that mercurial poisoning produces a subacute parenchymatous nephri is. Following this, c lc reous infarcts are to be found in the cortex. The ca'cium salts are deposited in the epithelial cells. As to how these salts are deposited, there are two theories: (1) That there is first a necrosis followed by calcareous degeneration, and (2) that the salts are dissolved from the bones and then deposited, in the kidneys. His conclusions from experiments are that, if sublimate be injected into the renal cortex, there is produced a deposit of lime salts in the canaliculi about the seat of injection. This occurs only after some days and following phenomena of necrosis of the cortical elements. These phenomena are similar to those observed after the drug has been injected into the blood. The deposit may be slight, or may produce calcareous cylinders filling the canaliculi.—*Lo Sperimentale*, June, 1904.

Diagnostic and Prognostic Significance of the Pulsus Paradoxus.—Giovanni Galli questions the opinion of Kussmaul that the pulsus paradoxus is a pathognomonic sign of sclerosis of the modiastino-pericardium. He states that the pulsus paradoxus is found in a great variety of diseases; it is found in all the diseases of the heart and vessels, the lungs, in laryngeal stenosis of diphtheria, nephritis, infective diseases, in convalescence, etc. He gives the greatest importance in the production of the pulsus paradoxus to the pulmonary traction. The heart feels the influence of this, which tends to maintain it in a continuous diastole. This pulmonary traction is determined by the elasticity of the alveoli. He says that the pulsus paradoxus should be divided into two groups, that of Kussmual, associated with engorgement of the jugular veins, and characteristic of mediastino-pericarditic sclerosis; and pulsus paradoxus dependent on diminished myocardial resistance, on a fun tional or anatomical alteration of the heart, and encountered in many diseases as well as in convalescence. When this exists, the prognosis should be cautious and tentative. The pulsus paradoxus of functional nature and of short duration, is due to intestinal autointoxica-

tion, to poisoning by the products of fatigue, or to the action of toxic drugs.—*Il Policlinico*, July, 1904.

The Vitality of Germs on the Decks of Ships.—C. M. Belli has made valuable experiments as to the vitality of germs that have been deposited on the various parts of sea-going ships. The larger number of germs are found in the dust of the corridors, some on the carpets, and very few in the kitchen. This results from the different conditions of exposure to the air and sun, as well as the materials used for covering the floors. He made his experiments by depositing in various places Bacillus mesentericus, vulgatus, and prodigiosus, and sarcina lute. The decks were then washed as usual, and culture tests were then made. He concludes as follows: (1) Germs on the deck of a ship die naturally, those that bear no spores quickly, those that have spores, after a time; conditions of humidity and light have much influence on their death. (2) Washing with sea-water has a very limited action on the non-spore bearing germs, because they die at any rate; against the most resistant it is quite sufficient; hence, this is an excellent method of cleansing. (3) Washing with lye has no advantage over sea-water except as it acts as a solution of soap, and has a very limited disinfectant action; in case of epidemics the lye must remain in contact with the wood for a long time to have any effect.—*Annali di Medicina Navale*, June, 1904.

Dermoid Cysts of both Ovaries in Two Sisters.—François Hue reports these interesting cases. The first patient was a woman of twenty-six years, with an excellent family history. The patient, before marriage, had never suffered with any abdominal trouble. In the five years of her marriage she had had five pregnancies. The last pregnancy had ended at full term, five months previously, and that labor had been difficult, as if some obstacle hindered expulsion. For four years the patient had suffered with abdominal symptoms. A mass could now be palpated, and the abdomen was as large as would be normal at a six months' pregnancy. Exploration was slightly painful. The tumor was round and slightly fluctuating. On vaginal examination the uterus was found to be movable. Menstruation had not taken place since the last labor, although this might be accounted for by the fact that the patient had been nursing her infant. Cyst of the ovary was diagnosed and operation was performed. It was discovered that there were two cysts—one of each ovary. The contents of the cysts were characteristic. It is now five and one-half years after the operation and the patient is in perfect health. Five years after the first patient presented herself for treatment, her young sister, eighteen years old, was taken with great pain in the abdomen. Examination disclosed an abdominal tumor which, at operation, proved to be identical with that of her sister's. An ovarian cyst of each ovary was removed. Since the operation her health has been perfect, but the menses have never appeared. These are most interesting cases, and the writer presents them without comment.—*La Revue Médicale de Normandie*, July 25, 1904.

Ankylostomiasis.—M. Dopter reviews first the geographical distribution of this affection. In Africa it attacks the population of the western coast. In Asia its frequency is noted particularly in India. In America it occurs frequently, being especially common in Brazil. In the United States it is seen in Louisiana and Georgia. It is far from being unknown in Europe. It is especially common in Italy, chiefly in the north, where the parasite finds in the numerous tunnels which burrow through the mountains, all the conditions favorable for its development. It is far from being rare in France. Among the most important symptoms of this affection is anæmia. But before reaching this stage the initial phenomena are always those relating to some digestive trouble. After anæmia has once developed, it becomes rapidly more and more profound, and is accompanied by cachexia. Œdema appears. Functional troubles become marked. Vertigo and palpitation occur. The pulse becomes irregular, soft, and rapid. The temperature is rarely elevated. At autopsy, the body is not found to be emaciated. The œdema and anæmia are generalized. The mucosa of the small intestine is catarrhal, it is covered with mucus and is often very bloody. Ankylostomiasis is a parasitic malady, and is doubtless transmissible. Proofs of this are found in the history of the affection and in the various epidemics which have occurred. A mine has been known to become contaminated after the arrival of an infected workman. Laboratories have become contaminated. The disease has disappeared partly or wholly under the influence of prophylactic measures which consisted in isolating the patient and all objects that might have become contaminated. Proper prophylaxis, then, should always be attended to when there is any danger of this infection.—*Gazette des Hôpitaux Civils et Militaires*, July 23, 1904.

Surgical Suggestions.

Decubitus.—In the prevention or treatment of decubitus, Straetter uses a large pad of felt with a hole cut in it to correspond with the site of the denuded spot. The pad is painted with glue and stuck to the patient's back—in other words, a greatly enlarged corn protector.

The Treatment of Acute Trachoma by Excision of the Diseased Tissue and Brushing.—The method adopted is to evert the upper cul-de-sac completely by means of forceps, to divide the conjunctiva from one end to the other, and lastly to excise the submucous tissue where diseased by means of small curved scissors. Into the raw surface a solution of sublimate, 1 in 500, is brushed. The after-treatment consists in free irrigation of the eyes.—Chedoudi, *La Clinique Ophthalmologique*.

Speed in Operation.—Learn to operate rapidly. An operator who is a dissector handicaps by his tedious delvings the safety of his patients.

Angioma.—Pass catgut in a zig-zag manner first below the skin, then under the base of the humor, then again beneath the skin and underneath the humor until the mass is included in a continuous suture. Draw tight and close at the point of entrance. No gangrene follows, as the blood supply is not all cut off. When the tumor is diminished to a connective tissue nodule the latter is excised.—Beck.

Hour-glass Stomach.—Moynihan finds that in many cases there is narrowing also of the pylorus, showing that gastric ulcer is often multiple. Hence in many cases no single operation will suffice. If a gastroenterostomy is performed from the cardiac pouch, the pyloric pouch remains undrained. In many cases a double operation is required—gastroenterostomy from both pouches, gastroplasty combined with gastroenterostomy from the pyloric pouch, gastrogastrostomy with gastroenterostomy, or gastroplasty and pyloroplasty.—*British Medical Journal*.

Fibroma of the Tunica Vaginalis.—From the study of a case which came to operation, Balloch says the following conclusions may be drawn: (1) That, like other serous cavities, the cavity of the tunica vaginalis may be the seat of fibrous growths. (2) That irritation is an important factor in their production. (3) That they spring originally from the subserous connective tissue, but may become detached and lie loose in the cavity. (4) That they are mostly of the variety known as soft fibroma. (5) That they are prone to myxomatous and fatty degenerations. (6) That the testicle may be affected by the same forms of degeneration. (7) That the growths are generally minute, the present case being unique both as to the number and the size of the tumors. (8) That excision is the only effectual remedy. (9) That, as the testicle is liable to be affected, the propriety of removing it with the growths should be considered.—*Annals of Surgery*.

The Efficacy of Anti-mosquito Campaigns in the prophylaxis of mosquito-borne diseases was well illustrated last fall in Laredo, Tex. That city is situated on both banks of the Rio Grande river, partly in Texas and partly in Mexico. In September yellow fever appeared in the city. The medical officers of the U. S. Government took charge of the measures in the Texas portion of the town; patients were screened, breeding places for mosquitos were oiled, and infected premises were disinfected to kill the insects. As a result, in the Texas portion of the city only 10 per cent. of the inhabitants were affected, while in the Mexican quarter 50 per cent. suffered. In November an officer of the Marine Hospital Service investigated the local conditions and was unable to discover any stegomyiæ either in pupal, larval, or adult stages in the American portion of the town.—*Clinical Review*.

Book Reviews.

A Reference Handbook of the Medical Sciences, Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. A New Edition, completely Revised and Rewritten. Edited by Albert H. Buck, M.D., New York City. Volume VIII. Illustrated by Chromolithographs and four hundred and thirty-five Half-tone and Wood Engravings. New York: William Wood and Company, 1904.

With the appearance of this volume Dr. Buck's great undertaking comes to a successful close. The titles include everything in alphabetical order between Umbelliferæ and Zymolysis, in addition to a number of articles prepared too late for insertion in their proper place, and so of necessity consigned to an appendix. The most important subjects treated of here are: Urethra, Urine, Uterus, Vaccination, Vagina, Variation, Veins, Vital Statistics, Water, Yellow Fever, and in the appendix, Arsenic, Asiatic Cholera, Bacteriological Technique, Hæmolysis, Peritonitis, Protozoa, and Anatomy of the Skin. A very complete and satisfactory index of the entire work by Dr. R. J. E. Scott fills 185 pages at the end of the volume.

A review of a work of this kind, in the necessarily limited space allotted to book notices, is practically impossible. Any analysis of all the articles is, of course, out of the question, and it would give but little idea of the work as a whole to review at length any individual article. Those who are familiar with the first edition of the Handbook already know its plan and scope, and for them it will suffice to say that there is no change in the character of the work, although nearly all the articles have been rewritten or so thoroughly revised as to bring them fully up to date, and many new subjects have been introduced. It is especially in the field of bacteriology, or rather of microparasitology, that the most conspicuous additions have been made, for this branch of medical science was in its infancy when the first edition of the Handbook was written. Radiology was unknown and, one may say, unthought of when the supplement to the first edition was published; this is fully treated of in all its forms—*x*-rays, the Finsen light, radium, and the d'Arsonval current—in the volumes before us. Immunity and serum therapy, the outcome of pathogenic bacteriology, are other new subjects which have received ample discussion. A few minor topics, such as Banti's disease and Talma's operation, are not to be found in the index, and some others which might profitably have been considered in separate articles are referred to only incidentally in the discussion of other subjects. It is fair to say, however, that a careful and critical search has brought to light very few omissions of the sort, while the study which the index has received for the purpose of discovering omissions has revealed a wealth of other topics seldom discussed by writers in medicine and yet, for that very reason, all the more necessary to be included in the scheme of a medical encyclopedia. The editor is richly endowed with what, in the case of a newspaper editor, would be called "a nose for news," and in all the vast domain of medicine very little has escaped him. No medical work in the English language, or indeed in any language, not excepting German, is so truly encyclopedic as this, and to the practitioner—family physician or specialist—who would inform himself on any subject connected with his science, the Handbook is surely indispensable.

The Doctor's Leisure Hour, Facts and Fancies of Interest to the Doctor and His Patient. Arranged by Porter Davis, M.D. Chicago, Akron, O., New York: The Saalfield Publishing Co., 1904.

This is the first volume of a proposed series of twelve, entitled "The Doctor's Recreation Series," edited by Charles Wells Moulton. It is a well-arranged collection of anecdotes, witticisms, verses, and short stories relating to the doctor, his art, and the patient. The extracts are grouped into various chapters, headed The Student, The Professor, The Young Doctor, The Diagnosis, The Disease, The Patient, Some Famous Doctors, The Doctor's Wife, The Microbe, Christian Science, The Quack, Our Friend the Apothecary, Until the Doctor Comes, The Fee, etc. As a rule, we dislike collections of this sort, for there is much said and written about the practice of medicine which is stupid beyond all belief, and the collector, for some inscrutable reason—probably because he is stupid—unerringly picks out the most vapid jokes, the dullest stories, and the purest doggerel, and they go out into the world as the doctor's idea of himself and his work. But this book is not of the usual kind. Dr. Davis has discrimination and a sense of the appropriate, and one can read here and there in the collection with interest and amusement. The collection is made up of selections from almost everywhere, from the writings of Lover, Jerome K. Jerome, William L. Alden, John Kendrick Bangs, Ian MacLaren, poems by Burns, Weir Mitchell, James Ball Naylor, squibs from *Life*, *Puck*, *Judge*, *Punch*, and from the funny column of the daily papers, all arranged in a well-printed and well bound volume suitable for the physician's library or the table of his waiting-room. If the succeeding volumes of the series are as good as the first, the set will be creditable to both editor and publisher and one that the doctor will want.

Adolescence: Its Psychology and Its Relations to Physiology, Anthropology, Sociology, Sex, Crime, Religion, and Education. By G. Stanley Hall, Ph.D., LL.D., President of Clark University and Professor of Psychology and Pedagogy. New York: D. Appleton & Company, 1904.

Dr. Hall has won well-merited renown as an exponent of psychology, and the two volumes recently published by him on Adolescence fully sustain his reputation. A study of this subject is perhaps the most important phase of psychology, for in the period of life known as adolescence, character is formed for good or evil. Thus in this stage of human development, all its relations require close investigation in order to be able to avoid the shoals and quicksands that beset the course on every side. Especially is this the case in the present day and in the United States. The American youth of both sexes is eminently precocious from the very nature of things. The environment tends to render the passage from youth to maturity a leap rather than a gradual growth. The restlessness and nervous energy of a new country is in the very air, and for youth there is no repose, nor do the arts, legends, romance, idealization enter into the equipment of American youths and maidens as a preparation for their life work. The work of Dr. Hall is ambitious in its general scheme, and attempts a fairly full survey of pedagogic matter and method for the age from fourteen to twenty-four, and also to some extent for earlier and later years. Chapter III, one of the longest of the book, deals with motor education, grouped under four great divisions, and will-training. Chapter IV treats of diseases of body and mind, the writer asserting that the physical and mental ailments and diseases of adolescence are a new field of pathology. Modern concepts and forms of dementia præcox are discussed at some length. Referring to that much disputed point, the alleged analogy between genius and insanity, the author says: "Both are prone to eccentricity; often have a disordered, emotional basis, or an insane temperament; are likely to produce inferior children; to occur in the same family, etc. Whether mattoids or sports, geniuses are always the apotheosis of adolescence." Instructive chapters are those on sexual development; its dangers and hygiene in boys, and periodicity. Both questions are fully considered, and valuable advice as to preserving the health during these periods is tendered. The chapter on adolescence in literature, biography, and history has a distinctly literary flavor, and provides illuminating reading concerning the youth of great writers. Chapters X and XI are concerned with the evolution and the feelings and instincts characteristic of normal adolescence and adolescent love. Chapters XVI and XVII are devoted to intellectual development and education and adolescent girls and their education. The subject of education is nowadays a burning one, and much may be learned by a study of Dr. Hall's views on the situation. The work of Dr. Hall is, it may be said without exaggeration, a great one throughout. Those parts dealing with physiology and matters pertaining to disease or medicine generally are written with an accurate technical knowledge. The language used in the book is well chosen and direct. Dr. Hall has the rare art of enlivening the dry bones of scientific lore with the charm of eloquent diction and pleasing style.

Epilepsy and Its Treatment. By William P. Spratling, M.D., Medical Superintendent of the Craig Colony for Epileptics, at Sonyea, N. Y. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

There is probably no one, in the United States at least, better equipped and better fitted by reason of his opportunities and their intelligent utilization to prepare a monograph on the subject of epilepsy than is Dr. Spratling, and the present volume is but a realization of the promise held out by his numerous scattered papers dealing with the same subject.

In the volume before us an introductory note deals with the many synonyms of epilepsy, the mystery of whose nature has not even yet been cleared up. Chapter I is devoted to a definition of the disorder and Chapter II to a classification of the various types in which it appears, including also an elaborate scheme of examination. In successive chapters there are then discussed the question of the frequency of the disease, its relation to age, sex, race and occupation, its etiology, the types of seizures, the epileptic status, the forms of epileptic aura, the sequels of the convulsion, diagnosis, prognosis, pathology, general medical and surgical treatment, psychological and medico-legal aspects. A full index of 18 pages is added.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventy-Second Annual Meeting, Held at Oxford, July 26, 27 28, and 29, 1904.

(Special Report to the MEDICAL RECORD.)

(Continued from page 318.)

SECTION OF TROPICAL DISEASES.

The Fallacy of Finality.—Dr. ALEXANDER CROMBIE, President of the Section, delivered the opening address. He said that just ten years ago, when opening the Section of Medicine and Pathology at the Indian Medical Congress of 1894 he selected "Indian Fevers" as the subject of his presidential address. He hoped to be excused if he now delayed the commencement of the work of the section by a short review of some of the opinions expressed on that occasion in the light of our present more advanced knowledge. He had attempted to differentiate certain fevers of the continued type. The criticism of clinicians had on the whole been favorable to the belief in the occurrence in hot climates of fevers of a continued type other than typhoid and malarial remittent, but the opinions of our laboratory confrères had been almost uncompromisingly opposed to it. Notwithstanding official returns to the contrary, which showed an overwhelming majority of admissions for malarial fevers, "ague" was not the most prevalent type of fever in any of the parts of India where he practised his profession. The commonest type of fever was what he had elsewhere called a "single paroxysm fever." The paroxysm might be of a few hours' or a few days' duration, but it was a single paroxysm, and had no tendency to recur. If it lasted a few hours it was called "ephemeral fever," if a day or two, it was called "febricula;" if several days, it was known as "simple continued fever." These attacks of fever gave no clinical evidence of periodicity, such as was caused by the life-cycle of a parasite renewing itself at frequent intervals in the blood. No malarial parasites could be found in such cases, and the patients all recovered without quinine. But since his paper was written these cases of a single pyrexial paroxysm had, nevertheless, been by many regarded as essentially malarial in their nature. Rogers said they were all malarial because they showed the mononuclear increase of malaria and were cured by quinine. But he did not say that he found the malarial parasite present in any of them. The fact that they ceased after quinine was no evidence of their malarial nature, because they are essentially fevers of a single paroxysm and ceased equally promptly without quinine. The mononuclear increase could no longer be held to be conclusive evidence of recent malarial infection, therefore nothing remained to support the contention that these cases were all of a malarial nature.

In September, 1902, Captain James examined a number of cases admitted or detained for ague at Mian Mir. He found malarial parasites in 45 per cent. of these cases. No quinine was administered to a number of men in whom no parasites were found. All of them recovered in from one to three days. From this, and from the fact that several examinations in each case failed to show the presence of parasites, Captain James concluded that these cases were not due to malaria, though usually entered as such in the returns.

Similarly, writing in Bombay in February, 1904, Mr. A. Powell bore testimony to the same effect. We must therefore conclude that a large proportion of the febrile attacks of hot climates must still be included in the terms "febricula" and "simple continued fevers," and that the evidence that they are malarial is inadmissible.

Another form of fever which he had called "non-malarial remittent" was a fever of considerable severity, duration and mortality, lasting on an average six weeks, if not fatal at an earlier period. He was never able to find malarial parasites in such cases, and quinine was not only ineffectual but obviously harmful. The late Dr. Hughes and Dr. Edmondston Charles contended that this "non-malarial remittent" was in reality Mediterranean fever, and, indeed, it was announced that the sedimentation test for Malta fever had been successfully applied to such cases in India, and that agglutination occurred in every specimen of blood sent from fever cases in Assam. They also held that kâla-azár was epidemic Malta fever—a theory which has now been abandoned.

As a result of the study of continued and remittent fevers by modern blood tests, Rogers was driven to the conclusion that only two forms of fever existed in Lower Bengal, namely, typhoid and malarial remittent. The so-called "non-malarial remittent" in natives was, according to him, shown by the serum test to be nothing but typhoid fever. Unfortunately for this pronouncement, the ink with which it was written was hardly dry when Leishman made the discovery of the bodies, now associated with his name, in the spleen of cases of fever from dum-dum, which were neither malarial nor typhoid, and kâla-azár, which Rogers thought was a contagious form of malarial fever, was now shown to be a form of "non-malarial remittent" associated with the same bodies.

He did not bring these points forward as a parade of superior clinical sagacity. Indeed, the clinical character of the cases associated with Leishman's bodies was very often apparently quite different from that of the fever he had called "non-malarial remittent." His object was to point out the fallacies which lay in the way of investigators. The fallacy he chiefly wished to allude to was the fallacy of finality, the fallacy that every step made in advance is final, and that every fact of medicine must be brought into line with it for the reason that there was nothing beyond. It was a fallacy which had marred the progress of medicine ever since it started on its journey. To go no further back than the middle of last century we knew that previous to that time there was only one kind of non-malarial fever, and that was typhus. In vain did clinicians and pathologists point out that there existed another type of fever of more insidious character and accompanied by ulcerations of the small intestine, which was clinically and pathologically distinct. It was not till fourteen years later, when Jenner's classical labors showed it to European practitioners, that they had ears to hear and eyes to see that the "typhoid fever" of the English, the abdominal typhus of the continent, was a distinct pathological and clinical entity.

But it was thought this step was final; every fever that was not malarial must be either typhus or enteric, and Mediterranean fever had to be included in one or other of these categories. Then came Bruce to show us that it was as distinct bacteriologically as it was clinically and pathologically from either.

At last we had got to the end of everything, and every fever that was not malarial or typhoid was Malta fever. In proof of this opinion came reports of serum tests from Upper India and Assam entirely corroborative of it, and it was clinched by the discovery of the clinical significance of the leucocyte count.

Rogers was the great apostle of the leucocyte count. He had arrived at finality: an increase of the percentage of lymphocytes indicated typhoid; that of the large mononuclears, malarial fever. The presence of the malarial parasite was of little comparative importance, and, in fact, he found it in less than 25 per cent. of the cases he diagnosed as malarial by the differential leucocyte count. Now we know that the presence of an increased percentage of mononuclears is not confined to malarial infection. It had been found in the spotted fever of the Rocky Mountains, in the fever of trypanosomiasis, in blackwater fever, and in that associated with Leishman's bodies. Indeed, Rogers himself admitted that "if the new bodies are not a form of malarial organism then it is evident that a large mononuclear increase is not diagnostic of malaria, but rather an indication of the presence of a protozoal as opposed to a bacterial invasion of the system."

Arguments have been brought forward to prove that the so-called "non-malarial remittent" is nothing more than typhoid fever. But he required something more than an increased percentage of lymphocytes, or even the Widal reaction, to convince him that enteric is a common fever among natives of lower Bengal. It had yet to be proved that typhoid was the only fever in which an increased lymphocyte percentage occurred, and until that was done all argument founded on that assumption was a mere begging of the question. We have it on record that one of Rogers' predecessors in the appointment of pathologist to the Medical College Hospital, Calcutta, did not see the ulceration of the intestine (pathognomonic of enteric fever) in a native of Lower Bengal during the ten years of his tenure of office, and the absence of confirmation of his opinion by post-mortem examination was a serious omission in Dr. Rogers' paper.

In all the larger towns of India there was a peculiar type of fever which ran the course of a mild typhoid of from three to four weeks' duration, but which had none of the clinical symptoms of that disease. It was known under the names of "Calcutta fever," "Bombay fever," etc. He provisionally called it "urban fever" in 1894, but now he called it "bastard typhoid," and he regarded it as a peculiar form of typhoid fever, because in a case he had the opportunity of examining before leaving Calcutta he obtained the Widal reaction, and as this was a fever of Europeans, the same objection did not exist to accepting this evidence as it does in the case of natives. Rogers also stated that he found this reaction in every case of continued fever in the wards of the European General Hospital. His experience in connection with the typhoid fever of the South-African War, which showed several very distinct deviations from the ordinary classical enteric of the text-books—namely, the often copious eruptions, the frequency of thrombosis and of muco-enteritis as a sequela—led him to think that typhoid was generally a mixed infection, the symptoms and severity varying with the amount and quality of the mixture, and it was not impossible that the peculiar type which occurred in the large cities of India might turn out to be a pure infection with Eberth's bacillus, and might thus form the bed-rock on which the more classical cases were built up by additions of other intestinal flora.

Discussion on Trypanosomiasis.—Col. David Bruce, R.A.M.C., opened the discussion on trypanosomiasis. He began by discussing the statements on this subject which had been made at the Swansea meeting of the British Medical Association a year ago. He said that 80 per cent. of the propositions laid down at the Swansea meeting had proved incorrect, and trusted that the conclusions of this year would not show such a high rate of mortality. Only one conclusion laid down at the last meeting he considered to be correct—the failure of treatment. He was going to lay down the following propositions: That the trypanosoma found in the blood and that found in the cerebro-spinal fluid in sleeping sickness are identical; that the so-called trypanosoma fever is the first stage of sleeping sickness; that neither the native nor the European is immune to this disease, and that the mortality is 100 per cent. in both colored and uncolored races. Up to the present no evidence had been brought forward to show that any of the lower animals took any part in the spread of the disease. It was quite true that many mammals besides man were capable of being infected artificially by this disease, but he thought the enormous number of infected natives in the sleeping-sickness area showed that there was no need of the assistance of the lower animals to spread the disease. It had been stated that the trypanosomes lived in the blood of fresh-water fish, that these fish were suffered to lie on the surface of the water, and that some blood-sucking insect conveyed the trypanosomes from the fish to the human subject. Others speculated in the same way as to the crocodile playing a part in the dissemination of sleeping sickness. These were most ridiculous speculations. So far, Dutton and others had found it impossible to prove that there was any connection between *Glossina palpalis* and the spread of sleeping sickness on the west coast, but the evidence brought forward in Uganda was overwhelming. The distribution of the disease round the Victoria Nyanza and its islands was identical with that of the tsetse fly, *Glossina palpalis*. Where none of these flies existed there was no sleeping sickness.

It had recently been proved by Dr. Wiggins of Nairobi, in British East Africa, that several members of the genus *Glossina* were able to convey the virus of sleeping sickness from the sick to the healthy, and Greig and Gray found that *Glossina palpalis* was not only able to convey the trypanosomes of sleeping sickness, but also those of nagana or a disease of Uganda very closely related to nagana. These facts pointed to a grave danger, because if other species of the genus *Glossina* were able to carry the infection of sleeping sickness, the disease was likely to spread in all the tsetse-fly zones.

Although there was proof that the various species of *Glossina* could convey the trypanosomes of sleeping sickness, there was no proof that other genera of biting flies, such as *Stomoxys* and *Tabanus*, could carry the infection under natural conditions. Experiments on a huge scale had been going on in South Africa for many years in regard to the spread of nagana or the "tsetse-fly disease"; it was only where the tsetse fly, *Glossina morsitans*, or one of its allied species, *Glossina palidipes*, was found that this disease occurred. Outside that area there might be many other species of biting flies, but the disease never spread beyond the zone of the tsetse fly.

In speaking of the mode of transmission, Colonel Bruce again maintained that the transference of the parasites by the tsetse fly from one animal to another was purely mechanical, and he laid down as a proposition that *Trypanosoma gambiense* did not go through any metamorphosis in *Glossina palpalis*. The arguments in favor of the trypanosomes being conveyed by the tsetse-fly without any metamorphosis were: (1) The fact that the fly was not able to retain or did not retain its infective quality for more than forty-eight hours. No one had been able to infect a healthy animal by means of the tsetse fly for a longer period than forty-eight hours, and many attempts to convey the disease by means of the tsetse fly three days after the fly had fed on trypanosoma infected blood had always failed. If any metamorphosis analogous to that which the malarial parasite undergoes in the mosquito was undergone by the trypanosome in the tsetse fly, we would expect that the tsetse fly would not become infective until some time had elapsed from the last time of feeding. The mosquito in yellow fever did not become infective for some twelve days, and in the same way the mosquito in malaria took some days before it became infective. (2) The internal fluids and organs of very many tsetse flies had been examined to find out if any such metamorphosis took place, but no signs of any kind of metamorphosis were ever found.

The present evidence went to show that all the stages of the development of *Trypanosoma gambiense* took place in the human host, and thus it appeared that the trypanosome did not absolutely depend upon an intermediate host for its continuance.

In regard to measures of prevention, Colonel Bruce said that these should aim at preventing, as far as possible, the movement of natives from sleeping-sickness areas into any part of the country where any species of tsetse was found. Other measures would be the prevention, as far as possible, of the movement of healthy natives into sleeping-sickness areas; the evacuation, if possible, of these areas; and the destruction of the breeding-places of the tsetse flies and of the fly itself wherever possible.

Dr. David Nabarro said that as he had had the privilege of working with Colonel Bruce in Uganda on the Royal Society Commission, and assisting with the joint report on sleeping sickness published by the Royal Society, he

agreed with many of the propositions enunciated by Colonel Bruce. However, he did not think that in the present state of our knowledge we could say with certainty that so-called trypanosoma fever was only a stage of sleeping sickness. As regarded prognosis, he thought it was possible that man might become immunized after infection with trypanosoma, just as was the case with monkeys, dogs and other experimental animals. Colonel Bruce had stated that some of the natives in whose blood were found trypanosomata last year in Uganda have died from sleeping sickness, and that others were now suffering from the disease. He did not say, however, whether any of these natives who had the parasite in their blood last year failed to show it this year. A negative observation would, of course, require careful confirmation before being accepted.

With regard to the question whether any of the lower animals take any part in the spread of human trypanosomiasis, he said that during their researches in Uganda they had come across a disease in oxen in Entebbe, associated with a trypanosoma which, if not identical with, closely resembled the human trypanosoma, and he thought it just possible that these infected cattle in Entebbe might serve as a subsidiary source, in addition to infected natives whence the *Glossina palpalis* obtained its supply of trypanosomata. Together with Captain Greig, he had studied trypanosomata obtained from three other sources in Uganda and East Africa. Most of these animal trypanosomata were certainly different from the human, but further observations must be made before it could be said whether the diseases in animals to which they gave rise were already known, *e.g.* nagana, surra, etc.

Among the various propositions published by Colonel Bruce in the *British Medical Journal* of June 11 (supplement) it was stated that "several of the lower animals are susceptible to sleeping sickness by artificial inoculation." Dr. Nabarro thought this a very debatable point. Certainly several of their experimental monkeys died after being inoculated with blood and sleeping-sickness trypanosomata, but not with *undoubted* sleeping-sickness symptoms. Further, the brains of these monkeys did not show the typical naked-eye changes seen in sleeping sickness, nor was Dr. Mott, who examined several of these brains for them, able to find any traces of the perivascular lymphocytic infiltration which is so prominent a feature of the human sleeping-sickness brains.

Colonel Bruce had previously found in Zululand that the trypanosoma of nagana could be conveyed from sick to healthy animals after an interval of two days, but not of three days. He therefore concluded that the tsetse fly acted simply as the carrier of the parasite. It had been urged against this view that if one waited for eight, ten, or twelve days after a feed of blood containing trypanosomata, and then allowed the flies to bite a healthy animal one might get evidence of some metamorphosis of the trypanosoma in the body of the tsetse fly and of the presence of the parasite in its proboscis. Some of their feeding experiments were carried on for two months, and at the end of that time were negative. He thought that rather tended to show that, in those cases at any rate, there was no metamorphosis of the trypanosoma in *Glossina palpalis* with the formation of bodies analogous to the sporozoites of the malaria parasite in the mosquito.

Together with Captain Greig, he had experimented with other biting flies, namely, *Tabanidæ* and *Stomoxys*. The former could not be got to feed in captivity; the latter fed well, but in no case conveyed the infection. With regard to the specificity of the *Glossina palpalis* for the human trypanosoma, their experiments tended to show that other species of *Glossina* can convey this parasite. They also found that *Glossina palpalis* could carry the cattle trypanosome found at Jinga and the mule trypanosome. Dissection of flies at varying intervals after a feed yielded interesting results. The trypanosoma of sleeping sickness was found active and motile in the stomach contents of the fly seventy-one hours after the feed and the Jinga trypanosome one hundred hours after.

E. E. Austen, Zoological Department British Museum, read a paper, entitled "Supplementary Notes on the Tsetse Flies." He said that within the last few months a new species had been described under the name of *Glossina decorsei* by Dr. Emile Brumpt from specimens recently obtained by Dr. Decorse on the River Shari and the shores of Lake Chad. An examination of some of Dr. Decorse's specimens, however, showed that the supposed new species is in reality none other than *G. tachinoides* Westwood, which was described so long ago as the year 1850. In his monograph of the tsetse flies he (Mr. Austen) had described *Glossina tachinoides* as a variety of *G. palpalis*, but now he was bound to recognize that it was in reality a perfectly distinct species nearly related to *G. pallidipes*. The total number of species of tsetse flies known, therefore, amounted to eight.

Mr. Austen described the larva and pupa of *Glossina palpalis*, and said that it would seem probable that did we but know them, all the species of tsetse flies might be distinguished in the pupal stage by the characters afforded by the last segment.

Since the publication of his monograph, our knowledge of the distribution of *Glossina palpalis* had been considerably extended. Mr. W. Y. Wyndham found it on all the shores of the Albert Nyanza, and also on the Congo side of the Nile, about eight miles to the south of Wadelai. Dr. Brumpt encountered it at Nimule in the Nile Province of Uganda, to the west of the Nile in the Belgian enclave of Lado, and all down the Congo system from the source of the Welle to the mouth of the Congo. Eastward Dr. Brumpt had previously met with this species on the River Omo, which falls into the north of Lake Rudolf. Major Fred Smith found it all the way from Freetown to Kakena in the north of the Sierra Leone Protectorate. Dr. S. H. Jones found it in the Kadina River Valley, Northern Nigeria. Mr. W. F. Gowers collected it on the Forcados River, Southern Nigeria. Lastly, Dr. Dutton, Todd, and Christy met with it near Leopoldville, on the islands in Stanley Pool, and at other localities on the Lower Congo.

Contrary to what had been found to be the case with regard to *Glossina morsitans* in South Africa, *Gl. palpalis* did not appear to be dependent for its existence upon big game, and in Uganda, at any rate, the members of the Sleeping Sickness Commission seemed to have come to the conclusion that this species of tsetse fly subsisted largely upon human blood. Mr. Wyndham said: "The fly seems a rapid feeder, to judge from some caught on the men. They do not appear early in the morning, but continue until evening has well set in, and I caught one which was decidedly lively after dark by candle light." Dr. Cuthbert Christy found *Gl. palpalis* to be extremely common on the banks of the Congo and its tributaries, even on the smallest streams. He observed that it was commoner and more bloodthirsty at bridges and fords, or in places where ferry canoes were kept, or where the women go down to draw water or wash, than on either side further up or down the stream. On the large forest-covered island of Bamon, during the last week in January, *Gl. palpalis* were literally in myriads. The flies were most numerous within one hundred yards of the abrupt edge of the forest. Surrounding this forest were areas of marsh many miles in extent, where patches of solid gound were few, and where not a tsetse fly was to be found. In the dark, cool interior of the forest the tsetse fly, although not nearly so numerous or so bloodthirsty as at the margin, was still a pest. On one occasion Dr. Christy counted thirty-eight tsetse flies probing the body of a large monitor (*Varanus niloticus*) that he had shot only a few minutes before. In the blood of this animal were numbers of *Drepanidia*, but no trypanosomes. Having again visited Bamon Island at the end of April, Dr. Christy was surprised to find that on that occasion *Glossina palpalis* was conspicuous by its almost total absence, hardly a fly being

encountered, while the few that were seen appeared to have little inclination to bite. Probably this fly only sucked blood during certain months in the year.

Mr. Austen supplied much additional information concerning the distribution of the other species of *Glossina*, and in some cases mentioned new observations concerning their habits. Thus, according to Drs. Christy and Dutton, *Glossina fusca* bites at night. In conclusion, he pointed out that Dr. Brumpt believes that, in addition to trypanosomiasis in its various forms, tsetse flies must play an important part in the dissemination of other diseases due to hæmatozoa. Brumpt stated that in certain districts on the Upper Congo a filariasis due to *Filaria volvulus* is very widely spread; the disease occurred only among the canoe paddlers, *i.e.* among those who were most exposed to the bites of the tsetse flies. "The only cases hitherto known have been observed in the regions (such as Nigeria and Dahomey) in which tsetse flies abound. The lymphatic tumors caused by *Filaria volvulus* are met with, especially in the places toward which the lymphatics of the exposed regions converge."

Dr. Louis W. Sambon, Lecturer to the London School of Tropical Medicine, said he regretted he had not been able to hear the beginning of Colonel Bruce's paper. With regard to the rôle played by the tsetse fly in the dissemination of human trypanosomiasis, he maintained that it was that of a true alternative post. If this were not so it would be difficult to understand why the disease was limited to the tsetse zones and why it was not disseminated by other blood-sucking insects known to be capable of transmitting various protozoal organisms and, in some cases, trypanosomes. It was not exact to say that the idea of a term of life within the body of the fly was merely based on the analogy offered by the life history of the malarial parasites, and it was perfectly ridiculous to object that the dissection of infected tsetse flies had not shown any forms of metamorphosis similar to those of the *Hæmamœbæ*.

The fostering rôle of the tsetse fly was forcibly suggested by the peculiar distribution and epidemiology of trypanosomiasis. But no surmise could be made as to the location of the parasites or the forms they might assume within the body of their insect host, because nothing was known of the bionomics of trypanosomes. Colonel Bruce and Dr. Nabarro stated that tsetse flies might convey the infection until forty-eight hours after feeding on an infected animal, but never after three days, and they argued therefrom that the rôle of the tsetse fly is entirely passive. But they made no experiments to ascertain whether the flies could transmit the infection after periods of eight, twelve, or fifteen days, neither did they try to find out whether the flies were infective on emerging from their pupa cases.

Over two years ago, the speaker had suggested that *Glossina palpalis*, and probably other West-African species of *Glossina*, acted as true alternative hosts of Castellani's trypanosoma, and taking into consideration the peculiar mode of reproduction of tsetse flies, he further suggested the possibility that the transmission of trypanosomiasis might take place not only directly by the fly that imbibed the blood of an infected person, but also through its progeny, as was known to be the case with ticks in Texas fever. Quite recently Professor Schaudinn had studied the life history of *Trypanosoma noctuæ*, a parasite of the little owl (*Athenæ noctuæ*), and he had proved that this trypanosoma was fostered and disseminated by a mosquito (*Culex pipiens*). During its term of life within the body of the mosquito *Trypanosoma noctuæ* passed through alternating periods of motility and rest. The active periods coincided with the feeding of the host, and were passed within the contents of the midgut, the resting periods coincided with the end of digestion, the parasites attached themselves to the epithelial cells of the midgut, some penetrating between the cells, or even between the cells and the tunica elastico muscularis. Later they passed into the colon, penetrated the intestinal wall, reached the circulation, and through the dorsal vessel some were carried forward into the lacunoma round the pumping organ, others were carried to the ovaries. Those carried forward passed into the pharynx by injuring the tunica elastico muscularis, which was delicate between the pumping organ and the pharyngeal valve. They subsequently passed into the blood of the avian host during the evacuation of the sucking reservoirs. The entire period of the migration of the parasites from their entry into the body of the mosquito to their exit from the latter occupied a period of from seven to eight days. The parasites that attained the ovaries penetrated the youngest eggs and went to rest within the vitellus. They remained in the gregarine condition during the entire development of the embryo. They subsequently passed into the larva and were found also in the perfect insect. The mosquito recently emerged from its pupa case did not seem able to transmit the infection by means of its first bite. According to Schaudinn's observations, it could infect birds only at the time of its third feed.

A New Trematode of Man.—H. F. Conyngham, L.R.C.P.I., Demonstrator London School of Tropical Medicine, read a paper describing a new trematode, *Amphistomum watsoni*. Several specimens of a new species of trematode were sent by Dr. Watson of N. Nigeria. They were found in the duodenum and upper part of the jejunum of a patient who died of starvation and diarrhœa. The patient was one of a gang of freed slaves brought from Adamawa, German West Africa, to Zola, Northern Nigeria. He was found to be suffering from diarrhœa. His stools were numerous, watery, and of a bilious color, but contained no blood or mucus. In the stools were found many reddish-yellow translucent gelatinous oval bodies. At the postmortem the jejunum was found to be full of these bodies, some alive and still adherent. The mucosa showed no hemorrhages, but appeared to be slightly red. The other parts of the bowel, as also the other organs, were normal. The parasite proved to be a species of amphistome, totally unlike the *Gastrodiscus hominis* of Lewis, so far the only one of the genus found in man, and also unlike any hitherto described as occurring in animals. Dr. Conyngham suggested that it should be called *Amphistomum watsoni*.

(To be Continued.)

NEW YORK PATHOLOGICAL SOCIETY

Stated Meeting, Held February 10, 1904.

Dr. Otto H. Schultze in the Chair.

A Case of Hemorrhagic Meningoencephalitis.—Dr. M. G. Schlapp reported this case. The patient was a child sixteen months old, whose family history was negative. The child had been well up to the 25th of December when a cough developed, also an acute rhinitis, and foul-smelling material was discharged from the nose. This condition lasted four or five days when the child developed convulsions, which appeared first on the left side, *i.e.* the left leg, arm, and face. Later they spread to the other side. The mother took the child to the hospital and she noticed that the fontanelles bulged and that there was an œdema about the eyes, nose, and forehead; this lasted only one hour when it disappeared. The convulsions became worse, and this caused the mother to bring the child to the Flower Hospital, where the fontanelles were punctured. A diagnosis was made of acute hydrocephalus. About an hour after the fontanelles were punctured the child died. The autopsy was performed by Dr. Schultze, who was only permitted to open the cranial cavity and take out the brain. He found on the lateral half of the hemisphere, extending from the anterior pole to the precuneus, a peculiar hemorrhage in the cortex; the hemorrhage discolored the brain, as was shown in the photographs presented. In the longitudinal sinus there was a thrombus. On section the case looked like one of nonpurulent hemorrhagic encephalitis. The hemorrhages were almost entirely confined to the cortex of the brain, having

a dotty appearance. This condition was unquestionably caused by a thrombus of the longitudinal sinus, and the thrombus was undoubtedly an infectious one. Besides the hemorrhages and thrombi there was a meningitis extending over the greater area of the brain and was of the cellular type, made up of cell infiltration of mononuclears, but no pus cells. There was a meningoencephalitis, caused either by the infectious condition causing the thrombi, or else the thrombi were secondary to the meningitis. He said it was possible that the infection might have passed through the lymph spaces into the longitudinal sinus and produced a thrombus; or it might have been produced through the blood-vessels as the meningitis was produced. He said that sometimes these conditions were taken for encephalitis when there was really a thrombosed condition with stasis.

A Case of Hemorrhagic Myelitis.—Dr. M. G. Schlapp reported the case of a man, forth-eight years old, who, two years previous to the time of seeing him, had an attack of malaria and who had always been sick since. About two months before his present trouble began he had an orchitis as the result of an injury. The testicle became much inflamed and was removed in California, his physician saying it was tuberculous. The wound healed kindly and the patient felt well. He took a trip to the mountains, where he "strained" himself. He took a long drive, had a chill, and felt weak in the legs. There developed a numbness in the soles of the feet and in the sacral region. The numbness became worse and extended to the middle of the thigh. He had no definite objective symptoms, only numbness, and a beginning myelitis was suspected. There was no temperature and the pulse was about 80. He was placed in bed and carefully watched. The day after the temperature became subnormal, 97.6°. He was kept in bed for several days and the numbness became worse and objective symptoms appeared. Certain sensory disturbances appeared. He had anæsthesia below the knee, which spread gradually up the thighs and to the region of the umbilicus, where it remained for two or three days and then spread to the arms, and the patient died from what might be supposed to be paralysis of the vagus, or respiratory-cardiac center. One and a half days prior to death the temperature became 103°. At autopsy the liver was found to be sclerosed. He had a pneumonia which had existed for several days before his death. There was also an acute parenchymatous nephritis. The bones and spinal column were normal. There was no meningitis or disturbances of the pelvic organs and no secondary infection could be found. From the second lumbar segment to the fourth cervical there were masses of small hemorrhages throughout the gray and white matter. A diagnosis was made of a hemorrhagic, non-purulent myelitis. There was no meningitis. He said these hemorrhagic conditions of the cord were not common. Evidently this condition was caused by some infection, probably some toxic infection. Cultures were made but found to be negative. The Gram stain was negative.

A Teratoma of the Broad Ligament.—Dr. Ferdinand M. Jeffries presented this specimen, which was a very unique one. It was removed from a girl, seventeen years old, a virgin. The history dated back nearly two days prior to operation, although since the operation the surgeon gleaned that she had been troubled for some time with constipation. On several occasions she had considerable pain, which was supposed to be connected with her constipation. Two days before the operation she consulted her family physician, but merely for constipation, and a laxative was given. He was called in the next day because of the great distress of the patient; there had been no action of the bowels. Examination revealed an enlargement in the left inguinal region, which he had noticed at the first operation. The laxative was again given. The next day, the enlargement persisting, he called in a surgeon, who advised operation. The bowels had not acted and she had been in a stage of collapse and some temperature before the surgeon's arrival. He went in through the cul-de-sac and found a hæmatoma. He got rid of this clot of blood and then found what appeared to be a membrane and he made up his mind that he was dealing with pus. He made an incision, and, instead of pus, he found a sero-sanguinous fluid containing a lot of fat, partially emulsified or saponified fat, he knew not which. He traced the condition along and then came upon a growth. It was found in the left inguinal region and attached to the broad ligament. It was removed from the cul-de-sac of Douglas. It was a dermoid cyst and about seven inches in diameter. Projecting into the cavity of the cyst was a mass about the size of a small fist and of very irregular comformation. This mass was covered with skin quite typical in character, which gave rise to innumerable hairs. There was one projection at the free extremity the mass looking very like a toe having nail and all. To one side of this was a smaller toe-like projection without nail. At the base of the mass were two small tit-like projections which might have been rudiments of upper extremities. The mass was cut into and was seen to contain true bone, and in which were toe-like masses that might have been taken for tarsus and metatarsus.

Cast of Bronchial Tube.—Dr. Ferdinand M. Jeffries presented this rare specimen which was more often read of in textbooks than seen in practice. It was a cast of a bronchial tube obtained from a case of plastic bronchitis.

Presentation of a Specimen of Urine Containing Amœbæ.—Dr. Jeffries presented this specimen, which was of great interest. He said he had seen amœbæ in the urine before, but had paid no attention to the occurrence, believing it to be due to contamination from the water used in washing the bottles, or unclean centrifugal tubes or pipette. In using a one-sixth objective seven or eight could be seen, some exceedingly large. The patient was a young man, thirty-five years old, who had the measles. He had a stricture and the urine contained pus. He reported the case in order to obtain some enlightenment regarding it. He said he could conceive how, in cases of amœbic dysentery, the amœba coli could get into the urine, but this specimen showed the proteus amœba. He was not prepared to tell the differences between these two, except to indicate the localities where they were found. They did not contain blood-cells. He had been able to find the amœba in amœbic dysentery and show the blood corpuscles. In the specimen there was nothing that looked like the chlorophile bodies. Motility was noted during the fresh state.

Dr. John H. Larkin, in discussing the first case presented by Dr. Jeffries, said he had seen a tumor of the labium which was undoubtedly a teratoma and differed from the one presented in conformity and size. It had existed for some time. The tumor seemed to be enclosed in a cyst cavity and several diagnoses had been made. Upon section, bone, parts of testicle, glandular elements, etc., were found.

Syphilitic Ulcer of the Stomach.—Dr. John H. Larkin presented this specimen and said that, in reviewing the literature of ulcer of the stomach supposed to be syphilitic in origin, if one went back a sufficient number of years he would be struck with the great rarity of the disease. In many of the cases reported, no record was made of syphilis occurring in other parts of the body, or of a bacteriological or microscopical examination being made. He said that Chiari had collected 243 cases of syphilis which came to autopsy and only two were evidently cases of ulcer of the stomach due to this trouble. Of these, 145 were hereditary and 98 acquired. Klebs had reported but one case. Wasselbaum reported but one case. Several doubtful cases were reported by Wagner. In 1894-'95 a writer had collected 86 cases of syphilis, 25 hereditary and 61 acquired, and, at autopsy, he only came across one case of syphilitic ulcer of the stomach. Until

we came down to Flexner's time it was shown that syphilitic ulcers of the stomach were not common. The case reported was the counterpart of Flexner's. Dieulafoy stated that this condition was more common than supposed but not seen often at autopsy. Einhorn had never seen a case at autopsy, although he said it was of common occurrence.

The patient was a woman, thirty-six years old, a prostitute, who gave a history of syphilis acquired three years prior. Before death she had been under the care of a local doctor for three months. She complained of no gastric symptoms at all. Three weeks before her death she complained of severe epigastric pain, nausea but no vomiting. Two weeks before her death she had vomiting and her stomach was washed out. It was not until one day before death that she had an extreme sharp pain in the epigastrium accompanied by vomiting. The next morning she had great distension of the abdomen and the surgeon was called in, who made a diagnosis of volvulus; other surgeons made other diagnoses and all were wrong. Within forty-eight hours after the onset of the acute symptoms she died. At autopsy, when the transverse colon was lifted, there was shown a perforation in the anterior surface of the stomach in the lesser curvature. It was a little, shot-like opening. It was sharp and well-cut and its base was made by the pancreas. It was cartilaginous and sharply circumscribed and turned in. It was covered with a grayish sort of membrane. There were multiple gummata in the liver, miliary in type. The intestines were covered by an acute fibrous exudate; when pulled off, there were shown little masses not unlike miliary tubercles. These masses were yellowish and surrounded by a translucent zone and looked like infective granulomata. The microscope disclosed the ordinary picture of multiple or miliary gumma. There were scattered zones of necrosis surrounded by zones of fibrous connective tissue, sharply circumscribed and distinct from the healthy tissue. Examination of the sections showed a marked obliterating endarteritis. The muscular coat at the edge of the ulcer was hypertrophied and separated by a cellular infiltration. Around the blood-vessels in the submucosa there was a small round cell infiltration. The submucosa was infiltrated in places by irregular cells. In the base of the ulcer were irregular masses of necrotic tissue. From the results of the microscopical and macroscopical examination there was no doubt but that the case was one of syphilitic ulcer of the stomach.

Syphilis of the Intestine.—Dr. JOHN H. LARKIN presented this specimen, which was removed from a German, forty years old, who had been admitted to St. Francis Hospital February 15. There was nothing of particular interest in his previous history. Some time ago he had a chancre which was followed by secondary symptoms and lesions. He was sent to the City Hospital, where he remained eight months, and then was discharged on account of a malignant growth of the liver. For six months he complained of constant pain in the abdomen. During the past three months he had had a sore in the anus. He lost 100 pounds in two years and complained of great weakness. Examination of the blood showed 8,000 leucocytes and 3,200,000 red cells. The liver was somewhat enlarged. On March 15 the abdominal symptoms became masked. On April 1 the patient died, extremely cachectic and markedly emaciated, the most he had ever seen at autopsy. The intestines were covered with spots which were circumferential. The condition was limited to nine feet of the small intestine extending from the ileocæcal valve. Along the mesentery and all the way round the mucous membrane there were wide patches with intervening mucous membrane, with eroded areas one-half to one and a half inches. With this were also found gummata of the liver and of the first part of the rectum, which was strictured. The microscope showed a loss of mucous membrane and its replacement by a round cell infiltration. The peritoneum was also involved. He could find no accurate report of any similar lesion in the intestines, and he thought this to be of remarkable occurrence. Microscopical slides were shown demonstrating the lesions.

A Case of Acute Pancreatitis.—Dr. JOHN H. LARKIN presented a specimen which was removed from a German, thirty-six years old. At 10 o'clock one Saturday night, while at work, he was seized with violent pains in the epigastrium, which were followed in twenty minutes by violent vomiting. He was placed in bed, where he remained till Sunday afternoon, when he was brought to the hospital. He was then almost moribund but still conscious, and complained of great pain and vomited. The pulse and temperature were subnormal. He vomited several times and soon died. He was a well-nourished man. There was no tympanites. One liter of bloody serum but no clots were found in the abdomen. In the colon and mesentery were found scattered about little punctate grayish masses perfectly diagnostic of pancreatitis. The pancreas was immensely enlarged and lay in a sac by itself. It was dark red in color. The omentum showed slightly punctate areas of fat necrosis, which were extremely numerous. Until recently the speaker had been at a loss to find out the causes of hemorrhagic pancreatitis. In 1897 he had reported a case even more extreme than this. He found gallstones in the common duct but paid no special attention to them. Of course, he now knew that gallstones played a very important part in lesions of the pancreas, as demonstrated by Opie and others. In the pancreatic and common bile duct he had found nine stones. The common duct was so dilated that he could introduce the little finger. Just before the entrance to the duodenum, there was found a cicatrix in the common duct. At the time of autopsy, in the common duct was a small stone. What happened Saturday night? he asked. He said it was probable that one stone dropped from the common duct in the ampulla and had plugged not only that but also the pancreatic duct. The stone was found at autopsy pouting out but it could not get out. In a review of the articles written on this subject, especially Opie's, thirteen cases were reported, and among these thirteen stones were found in the common duct in ten.

Dr. E. LIBMAN referred to the peculiar chocolate-colored blood which was quite characteristic of acute hemorrhagic pancreatitis.

The Bacteriology of the Blood in Typhoid Fever; a Report on Sixty Cases, and a Statistical Study.—Drs. WARREN COLEMAN and B. H. BUXTON presented this paper. Three years ago they attempted to study the bacteriology of the blood in cases of typhoid fever entering the Second Medical Division of Bellevue Hospital. They had records of 60 cases, and having collected 544 others from the literature, giving a total of 604 cases, they felt justified in making a detailed study of the results obtained. Their practice had been to distribute 10 c.c. of blood into four flasks, each containing 100 c.c. of broth and to inbubate at 37° C. So soon as the flask showed turbidity a hanging drop was made and, if bacilli were found a culture on agar was taken in glucose gelatin, litmus milk, neutral red agar, and other differentiating media. The culture was also tested for its other agglutinating properties in an active serum, and if it responded to all the tests was considered to be true typhoid. From the bacteriological point of view, a few specially interesting points had been brought out in the course of this study: (1) They were able to confirm the observation of others that when first isolated, typhoid bacilli reacted less readily to immune serum than they did later, or after having been grown in artificial media. (2) There were some, however, which were especially refractory, and this characteristic was often quite persistent, so that it might take several months of artificial culture before they could be agglutinated. (3) The serum of rabbits immunized to such refractory strains quickly acquired agglutinating powers but did not agglutinate its own strain any better than serum obtained by immunization with a strain which readily agglutinated. In other

words, they said that any good agglutinate would always agglutinate well and a bad, badly with any immune serum, no matter how it may have been obtained. Tables were then presented which showed the large proportion of 75 per cent. of 604 cases with bacilli in the blood at some stage of the disease. They stated that 85 examinations were made in the first week of the disease with positive results in 79, or 93 per cent. The earliest recorded positive result was obtained on the third day. During the second week, 189 examinations had been made with positive results in 151, or 76 per cent. One hundred and fifteen examinations were made in the third week with positive results in 65, or 56.52 per cent. Fifty-two examinations were made in the fourth week with positive results in 18, or 32.72 per cent. Thirty-seven examinations were made after the fourth week with positive results in 11, or 29.72 per cent. By this analysis the interesting fact was brought out that a large percentage of positive results was obtained in the first week with a steady decline thereafter. It therefore appeared that the earliest and principal seat of infection was the blood, and that the disease might be in truth regarded as a septicæmia. If this was true, they might call attention to the utter futility of attempting to treat this disease by the administration of intestinal antiseptics. Another interesting fact brought out was that the relapses, in all but three, or 14 per cent., the bacillus had been found in the blood indicating its reappearance. In 73 of the 604 cases, or 10 per cent., the bacillus was present in the blood before the serum reaction was obtained. It was well known that the serum reaction did not appear till the end of the first or in the second week of the disease, yet the blood was known to be swarming with bacilli. In many instances the serum reaction did not develop until later than the second week. In the average case of typhoid fever they stated that neither the agglutination reaction nor a bacteriological examination of the blood was necessary to the diagnosis. The disease was recognized long before either of these tests became known, and they believed that it was probable that except in large centers or university towns that the great majority of cases were diagnosed without these aids.

Dr. W. Gilman Thompson spoke of the great value of accurate differential tests, especially in two sorts of cases, those in which we were in doubt as to the early diagnosis and again those in which we might be in doubt quite late in the disease when we wished to know whether it was typhoid fever or some of the conditions for which it might be occasionally mistaken. With regard to the early diagnosis there was one objection, the test required several days for completion. He asked how soon after receiving the specimen could a positive result be guaranteed from an examination of the blood.

Dr. Buxton answered three days.

Dr. Thompson said that if the specimen was given on the fourth day, results then could not be had before the end of the first week. When the Widal test was first introduced he said it was interesting to see how quickly the results were obtained in the different institutions. Among 500 cases in 93 per cent. the Widal reaction was found during the active course of the disease and a large percentage during the first week. Lately the Widal reaction had not been returned either by the Board of Health or other trained observers except during the third or fourth week and occasionally during convalescence or during relapses. Therefore, he had discarded this test. The existence of septicæmia explained to him many of the phenomena of the disease, especially phlebitis, periostitis of the ribs, etc.

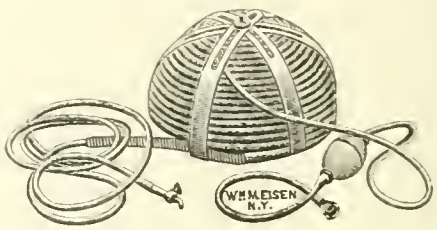
Treatment of Movable Kidney Without Surgical Intervention.—Dr. C. D. Aaron believes that 90 per cent. of patients suffering from movable kidney and associated proptoses can be relieved without an operation. Out of 442 cases, 215 absolutely recovered, 168 improved, and 59 did not improve or passed from observation.—*American Medicine.*

New Instruments.

A NEW HEAD COOLER.*

By FRIEDRICH GROSSE, M.D.,
NEW YORK.

About thirty years ago von Esmarch and Winternitz demonstrated experimentally that the temperature of every portion of the body, even of deep-seated parts, can be lowered by external applications. This applies also to the head. However, it was shown that this effect is by no means simple to attain. Formerly we had to resort to cold compresses, the ice cataplasma, or the time-honored ice-bag. As these instruments very often proved insufficient, special cooling apparatuses have been constructed on the principle of the siphon, *i.e.* cool water running through a system of pipes from an elevated reservoir into a receptacle below. The first apparatus of this kind was described by Winternitz. It was a double-walled rubber helmet, the two walls of which were sown together by a number of sutures in order to distribute the water equally. Later instruments consisted of one pipe several yards long, the middle part of which was rolled into a spiral, the whole being adapted in shape to the region of the body to be cooled. The first apparatus of this kind was of rubber and likewise an invention of Winternitz. His apparatus, however, was often compressed by the weight of the head; besides the material soon deteriorated. For these reasons Leiter recommended the same apparatus made of lead tubes, and at the



beginning of the nineties Gaertner took up the same idea, using his flexible aluminum tubes. But Leiter's instrument is too heavy and, like Gaertner's rigid, being displaced by any movement of the patient's head. The aluminum cap, in addition, cannot be repaired and must be replaced by a new one when damaged. Moreover, all apparatuses so far mentioned are of a definite, unalterable size, so that different caps are required for different heads.

All of these drawbacks are obviated by some modifications which I have made in a head-cooler, long in use in hydriatic institutions in Germany.

This instrument consists of six flexible, two-armed clasps of aluminum plate, the ends of which are cut out parallel to the long edges about as far as the middle and of a round metal plate an inch and a half in diameter. This middle piece bears in its center a screw-pivot. The openings of one arm of the clasps are brought over the pivot and fixed by a female screw. The fixed arms having been bent according to the patient's head, a rubber pipe is wound spirally between the fixed and loose arms of the clasps, and then the loose arms are also fastened around the pivot by means of a second screw. In the German instrument the center plate has a groove for each of the six clasps, so that these are immovable. However, it is advisable to have the plate smooth in order to allow the arms to be fastened irregularly, so that the three posterior (occipital) ones may lie closer together in order to give the rubber pipe more protection against compression by the heaviness of the head. According as the cut-out ends of the clasps are fastened around

*Demonstrated at a meeting of the German Medical Society, May, 1904.

the pivot at a greater or lesser distance from the center, the cap is made larger or smaller, and it is thus easy to adapt the cooler to any head. One end of the rubber pipe leaves the helmet in the middle, *i.e.* on the vertex, the other one at the periphery, both, of course, running in opposite directions. On this account the pipe might be kinked by a movement of the patient or the weight of the bedding. To prevent this interference, a semicircular piece of hard rubber tube is attached to the vertex, the concavity resting over the pivot. To avoid bending of the peripheral end, a piece of Gaertner's aluminum pipe is wrapped around the rubber pipe where it projects over the adjacent clasp. In the affluent pipe-end a suction-pump is inserted and the end loaded with a piece of lead, which keeps it at the bottom of the reservoir. Where the pipe curves over the brim, a hard rubber piece is attached to avoid compression. The effluent pipe ends in a metal cock which permits of regulation of the outflow and thus of the intensity of cooling.

The apparatus is rather light in weight, can be adapted to any head, and is almost unbreakable. To attain the full cooling effect, the patient's hair should be wetted and be covered by a moist compress. The cooler is easily handled and its management may be entrusted to even an untrained nurse. The cooling effect is regular and remarkably intense, so that in most cases water of 70° is sufficient.

407 West Forty-Sixth Street.

A CHEAP AND SERVICEABLE INSUFFLATOR.

By E. J. KEMPF, M.D.,
JASPER, IND.

The therapeutic value of medicated powders has always been recognized, and their use can be greatly increased if a little common sense be used in the home production of apparatus for the use of the powders.

Take an ounce quinine bottle, perforate the cork in two places, insert glass tubing which can very easily be bent over an alcohol flame, and to the end of the tube which is the longest in the bottle and shortest without, attach an ordinary atomizer bulb that can be bought at any drugstore for twenty-five cents.

The cost of this powder-blower need not be over thirty-five cents and a little labor, and it will be the equal of any powder-blower ever made. I have used it for the last fifteen years with the greatest satisfaction to myself and patients. The article in the Medical Record of November 21, 1903, on a new form of insufflator, by Sayer Hasbrouck, M.D., induced me to call the attention of the medical profession to this instrument which is easily made and at almost no expense.

A New System of Sewage Treatment.—A purely chemical system of sewage treatment, invented by Mr. Bayer, has been adopted by the City of Brünn, Moravia. The system is based upon the employment of a reagent composed of organic carbon, lime, and powdered zinc. These three substances are mixed in the proportion of one kilogram of carbon, twenty to thirty grams of lime, and ten of zinc dust per cubic meter of sewage. The purifying carbon is obtained by dry distillation in gas retorts of offal from abattoirs. After being well mixed with the reagent the sewage flows into a settling basin. The mud deposited is pumped into press filters, which compress it into cakes, which are distilled dry, so that part of the reagent can be recovered. After leaving the settling basin the water, yet turbid, runs to a filter composed of superposed layers of bricks, coke, and carbon. The filter effluent is conveyed to the river.—*London Engineer.*

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Prescriptions in the Irish Language.—The Royal Colleges of Physicians and Surgeons of Ireland have added Irish to the list of optional languages, one of which must be taken by each candidate at the preliminary examination held by the colleges. The following resolution, adopted at a recent meeting of the Kilkenny Branch of the Gaelic League, makes the action of the colleges more obvious: "*Resolved*, That we call on our elected representatives at the board of guardians to direct their employees to at once learn to speak the language of the Gael, and that Drs. Hackett and Morris write their prescriptions also in the Irish language under the pain of dismissal." Naturally the colleges did not want their future licentiates to be subject to instant dismissal for such gross ignorance. —*Medical Times and Gazette.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 20, 1904:

	Cases.	Deaths.
Measles	73	7
Diphtheria and croup	224	26
Scarlet fever	54	5
Smallpox	...	...
Varicella	18	...
Tuberculosis	420	130
Typhoid fever	120	20
Cerebrospinal meningitis	...	24

Tonsillitis a Cause of Acute Nephritis.—John Lovett. Morse reports several cases from which he thinks that it is evident that tonsillitis, whether of a severe or of a mild type, may be the cause of acute inflammation of the kidneys. It is probable that tonsillitis is more often followed by nephritis than is commonly supposed, and it is very likely that in many cases which are considered primary the infection enters through the tonsils, the local manifestations not being severe and having been forgotten. This being so, tonsillitis should not be looked upon, as it usually is, as a simple disease and of but little importance. A disease which can cause acute endocarditis and acute nephritis is certainly one worthy of consideration. The heart and urine in tonsillitis should therefore be examined as carefully as in rheumatism or scarlet fever, and the examination kept up for a time during the convolescence.—*Archives of Pediatrics.*

Thefts of Red Cross Funds.—The St. Petersburg correspondent of a London paper says there is great indignation over the malversion of the funds of the Red Cross. A number of impecunious aristocrats and court ladies were appointed to offices in the society, where they drew extravagant salaries and performed little, if any, work. In some cases these appointees drew salaries amounting to many thousands of dollars yearly. One member of the St. Petersburg committee borrowed an immense sum of money from the funds in order to gamble at the stock exchange. His speculations were unsuccessful, and the Czarina paid his debt to the society in order to avoid a scandal and save the thief who was a social favorite at the court. Similar scandals have occurred at Moscow, where two of the nobility appropriated the collections. One refused to pay the money back or to disclose the subscription list, but the other refunded $2,500. But, reports the London correspondent of *The Sun*, the crowning audacity has just been shown. The Czarina, the Queen of Denmark, the Queen of England, and other royal personages recently equipped a hospital train at St. Petersburg. It was fitted with every requisite for the comfort of the sick and wounded and was despatched with every box compartment carefully secured with the imperial seals. Soon after the train left St. Petersburg something induced the Czarina to telegraph to Moscow to make a careful inspection and this was done. The seals appeared to be undisturbed. One was broken as a test, and the contents of the compartment were found to be useless blocks of wood. The whole train was then examined. Everything of value had disappeared, and only blocks of wood were found.

A Case of Cavernous Angioma and of the Vastus Internus.—Corneloup calls attention to the rarity of these cases. The patient was a man of thirty-eight years. The family and personal history were both negative. At the age of eighteen, he had fallen and injured his knee. The trauma affected especially the inner aspect of the knee. The bruise was cauterized, and in about two weeks the wound had healed and nothing more was thought of it. About three years later a swelling was noted in this region. The tumor continued to grow slowly. It had no communication with the knee-joint. It was soft and completely irreducible. When the triceps contracted the tumor stood out prominently under the skin. A lipoma was thought of. There was no varix, and the patient had had no trouble with the circulation of the leg. It was later discovered that following the fatigue of a long walk the tumor grew gradually larger, became hard and more tense, and the skin became bluish, resembling the appearance of a varicose vein. The patient never complained of pain. Operation revealed an angioma occupying the lower extremity of the vastus internos. The tumor had numerous prolongations into the subcutaneous cellular tissue, and into the skin itself. Black blood escaped very abundantly in spite of an Esmarch bandage. The tumor was not clearly limited, but infiltrated the muscular tissue. It was removed as completely as possible, together with the varicosities. Recovery was rapid.—*Lyon Médical.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service during the week ended August 20, 1904.

ARTERIOSCLEROSIS OF THE SPINAL CORD.

BY JOSEPH COLLINS, M.D.,
AND
EDWIN G. ZABRISKIE, M.D.,
NEW YORK.

CEREBRAL arteriosclerosis causes symptoms that permit a diagnosis to be made with considerable certainty. Even comparatively mild forms of this disease of the blood-vessels of the brain are accompanied by symptoms that are considered fairly pathognomonic. Compared with other organic disease of the brain, cerebral arteriosclerosis is not uncommon. The subject has received much attention both from physicians and pathologists. These facts stand in marked contrast to spinal arteriosclerosis. Of it there is no description in the books, the symptoms that attend it have not been satisfactorily established, and it is usually diagnosticated according to its terminal condition, principally chronic myelitis, occasionally spinal apoplexy, and more rarely still, acute myelitis.

It is for this reason that we call attention to the following report, which we consider to be a typical case of spinal arteriosclerosis. Sclerotic degeneration of the blood-vessels of the spinal cord is much less common than that of the blood-vessels of the brain. But, nevertheless, we shall attempt to show that the time seems to be opportune to attempt to differentiate still further that most unsatisfactory and ill-understood pathological condition—chronic myelitis.

The first case that we shall describe is the following: Mr. H., a fireman, fifty-one years old, was in ordinary good health until toward the end of 1902. At that time he noticed that his legs were growing weak and that they tired easily. Later he complained of a jerking sensation in different parts of the lower extremities and at times of sharp pain, which might last from several minutes to two or three hours. The legs were the seat of a heavy, unwieldy sensation, but there was no "numbness" or other paræsthesia. About the same time he began to have difficulty in holding the urine, a symptom which steadily increased in severity. These symptoms continued until March 25, 1903, *i.e.* for three months, then he awakened one morning to find that he was unable to stand or walk and the sphincters of the bowels and bladder relaxed. There was no complaint of pain in the back or legs, no difficulty in moving the arms, in swallowing or in speaking. He says he was able to tell when his lower extremities were touched and he could feel the bed and the clothes. He was admitted to the City Hospital three weeks later and the following record was made on April 21, 1903:

The patient was a frail, emaciated man of medium height, who had the appearance of being fifty-five to sixty years of age. He was unable to stand or walk. When he was lying he could flex the thighs and the legs slowly and feebly. There was slight atrophy of the anterior and inner thigh muscles, more of the left than of the right side. The knee-jerks and ankle-jerks were absent. Irritation of the soles caused quite a typical Babinski phenomenon. The patient had fair strength in the upper extremities, but the arms tired very soon he said. The grip was moderate and alike in each hand. The motility of the face, head, and neck was not noticeably impaired. There was no difficulty in swallowing, and articulation was not defective. Tactile sensibility was slightly disordered in the lower extremities, although he could feel contact of the finger, the point of a pin, and the like. Sensibility was not so acute as normal; there was a quantitative diminution. Sensory perception was not delayed. There was a distinct zone of slight hyperæsthesia about as wide as the hand above the femoral trochanters. Above that sensibility was normal. There was no discernible impairment of thermal sensibility. The deep sensibility was not investigated. No part of the body was particularly tender upon pressure. A bed-sore existed over the sacrum, and there was excoriation of the genitals from constant dribbling of urine.

Examination of the chest showed shallow respiratory movements. Heart regular, weak, no murmurs, second sound accentuated. Examination of the abdomen showed that the liver and spleen were palpable, but were not enlarged. The abdominal reflexes, both upper and lower, were sluggish. The patient was slow of speech, likewise apparently of thought. He did not seem to show an adequate interest in his condition, still he was fully oriented and seemed to have a fair memory. His mental reflex was slow. There were indications in the peripheral blood-vessels and heart of a moderate degree of general arteriosclerosis. The peripheral vessels, such as the radial, were palpable, the walls thickened, the blood pressure increased.

The patient did not complain of pain while he was in the hospital, a period of four weeks, nor was there particular change of the patient's symptoms, subjective and objective, during this time. His mental state remained clear until forty-eight hours before death, when he became sleepy, stuporous, and comatose, dying apparently of cardiac weakness, which had set in simultaneously with the clouding of consciousness.

The symptoms then, in the order of their development, were as follows: (1) Weakness and easily induced fatigue of the legs; (2) peculiar sensations in the lower extremities, described as "jerky," "numbness," "heavy," and occasionally sharp pain; (3) progressive incontinence of urine; (4) progressive paraplegia.

The objective symptoms were atypical. What would seem to be a paradoxical condition existed; the tendon-jerks were absent and a Babinski phenomenon was present. The explanation of this is to be found in the condition of the anterior horns of the gray matter of the cord. Aside from this, the objective symptoms were those which are usually found in chronic transverse lesions of the cord, viz., slight disorder of sensibility, paraplegia, and trophic manifestations.

We were permitted to examine only the cerebro-

spinal axis. Nothing noteworthy was seen during the removal of the brain and cord save the deep and widespread involvement of the tissue about the bedsore. The naked eye appearance of the brain and cord was not abnormal. The principal stains used were the Marchi, Nissl, Van Giesen, and Weigert. In dividing the cord into different segments several areas in the lower dorsal segments were seen to contain small hemorrhages in the posterior horns on the right side and a similar condition in the left anterior horn. Otherwise nothing was noted macroscopically.

Microscopically, the arteries and veins were

Fig. 1. Section at the level of the eighth dorsal vertebra, showing the marked thickening of the media and adventitia with round cell increase. Zeiss, oc. No4, obj. DD.

everywhere throughout the cord and brain in process of arteriofibrosis. In the lower dorsal region especially, they were greatly distended with blood and thickened to several times their normal volume. The anatomical changes in the vessels, which consisted of an increase of connective tissue and loss of muscular fibers, were confined to the tunica media and propria, and in only a few instances did the tunica intima seem at all thickened (Fig. 1). In this region, also, we found many perivascular spaces filled with blood and distended vasa vasorum. The appearance of the vessels of the brain and medulla was strikingly different from that in the cord, for, in the former, the actual thickening was quite moderate and con-

Fig. 2. Section in the superior olivary region, showing the vessels moderately thickened as compared with those of the cord; also showing the enormous dilatation of the perivascular space. This is a fair type of the vessels of the medulla and brain. Zeiss, oc. No4, obj. DD.

fined chiefly to the propria. The vessels were distended and their lumina were wide, and everywhere a most remarkable enlargement of the perivascular spaces was apparent, showing that there must have been great intravascular pressure (Fig. 2). One often finds the vessels, especially in the medulla, surrounded by a loose, connective tissue, apparently springing from the tunica propria. These spaces were not filled with blood, as in the lower dorsal region. The actual hemorrhage occurred in and was limited to the ninth dorsal segment. Here the right posterior horn was the seat of a well-defined hemorrhage, which split the horn in its long axis, pushing out laterally and externally a short distance. The left anterior horn was also the seat of a well-defined hemorrhage, occupying almost the entire horn and breaking the tissue externally in places almost to the periphery (Fig. 3). Careful examination of the segments above and below this region failed to reveal anything but distended vessels with here and there perivascular spaces filled with small amounts of blood, involving also both crossed pyramidal tracts, more especially the right, from the fourth dorsal segment downward. There was very little glia cell infiltration, but it was apparently a chronic thickening of the glia fibers. The changes in the ventral horn cells were eccentric displacement of the nucleus and chromatolysis, varying in intensity on approaching the lesion. These changes were confined to the cells in the left anterior horn, of the ninth dorsal

Fig. 3. Section at the level of the ninth dorsal vertebra, showing the two hemorrhages, one in the right posterior horn, the other in the left anterior horn. Zeiss, oc. 2, obj. a. 2.

segment. The cells in the rest of the gray matter showed only an increase of pigment. We found even in the left anterior horn, not far from the seat of the lesion, apparently normal cells, while others presented the well-defined chromatolytic changes that have been described.

The secondary degenerations (studied by the Busch modification of the Marchi method) were of both ascending and descending type. Beginning at the lesion and going upward, we found the ninth dorsal segment the seat of the most diffuse changes. The blackened granules occupied almost the entire white matter externally to the horns, with the exception of small margins at the periphery just

Fig. 4. Ninth dorsal.

externally to the basis of the posterior horns, which were the seats of chronic sclerotic changes, and hence show no degenerated myeline. The only areas spared were the posterior, two-thirds of the right posterior column, and the median and posterior half of the left posterior column (Fig. 4). In the eighth dorsal segment the degeneration was beginning to be confined to Gower's column, with granules scattered throughout the entire anterolateral ground bundles, the anterior portion of the right posterior column, and a well-defined collection of granules occupying the lower portion of Goll's column on the right side. The left side showed only a few degenerated fibers lying along the posterior median fissure. The involvement of the Gower's columns and direct

cerebellar tracts was still very diffuse on the left side. The seventh dorsal segment showed practically the same areas of involvement as the eighth. In the sixth dorsal segment the commissural portion of the left posterior column was involved more than the right. The posterior portion of the Goll's column still showed well-defined changes. The changes in the direct cerebellar tracts, Gower's columns, and the anterior portion of the left anterolateral ground bundles, were quite diffuse. In the fifth dorsal segment there were practically the same changes in the posterior columns, while the Gower's bundles and the direct cerebellar tract had become more and more differentiated. In the fourth and third dorsal segment there was practically no

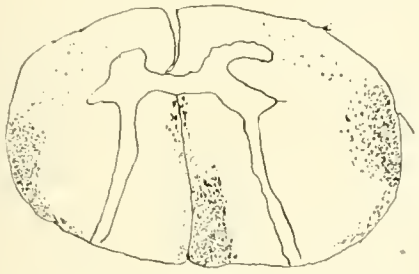

Fig. 5. First dorsal.

change. The second dorsal segment showed practically the same condition, except that there was a difference in the two sides, which consisted in the granules on the left side being heavier, larger, and more sharply defined than those on the right side. In the first dorsal segment (Fig. 5) the degenerated area in the commissural portions of the posterior columns consisted of only a few black granules. The Gower's tract seemed to be more involved on the right side than on the left. In the eighth cervical segment, the differentiation between the Gower's and the direct cerebellar tracts was well marked on both sides, but greater on the left than on the right. The seventh cervical showed practically the same changes. In the fifth cervical the degeneration in

Fig. 6. Medulla; region of lower olivary bodies.

Goll's column did not extend to the commissural portion of the posterior tract, occupying only two-thirds of the distance along the posterior fissure, and as it proceeded upward this area became more and more limited to the extreme posterior portion of the tract.

In the lowest portion of the medulla practically the same changes existed as in the first cervical segment. Then, as we proceed upward, we find the degenerated fibers occupying the nucleus gracilis along the posterior fissure, in the region of the inferior olivary bodies there are groups of scattered, blackened granules, confined to the posterior margin, and a well-defined group of blackened granules near the substantia gelatinosa. Next, at about the region of the middle of the olivary bodies, the black granules were seen within and scattered over the greater part of the corpora restiforma.

In the tenth dorsal segment, below the lesion, were large degenerated areas, occupying almost the entire anterolateral ground bundles, with the exception of the commissural areas of the anterior tracts and the marginal surface of the right anterior tract. The degenerations in the posterior columns were confined to two small faintly deliminated comma-shaped areas internal to the posterior horns.

In the eleventh dorsal the degenerated areas were more confined to the lateral pyramidal tracts and the anterior pyramidal tracts, the left anterior tract being more involved than the right. There were, however, scattered bundles, although

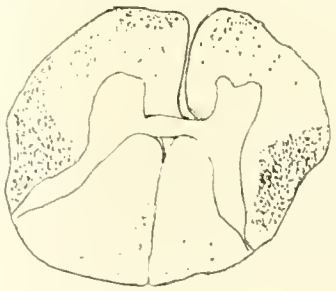

Fig. 7. First lumbar.

not so many, throughout the entire anterolateral ground bundles. The degenerated areas in the posterior columns were much smaller and not nearly so well-defined as in the tenth.

The twelfth dorsal showed the degeneration well limited to the pyramidal tracts, while the degeneration in the posterior columns consisted of a few scattered black granules.

In the first lumbar segment (Fig. 7) the lateral pyramidal tracts were smaller, and the degeneration in the posterior columns appeared closer to the posterior median fissure. There was, however, well-defined degeneration in the peripheral portion of the anterior column on the left side.

In the third lumbar segment the degeneration had almost completely disappeared from the anterior columns, while it began to take on a definite

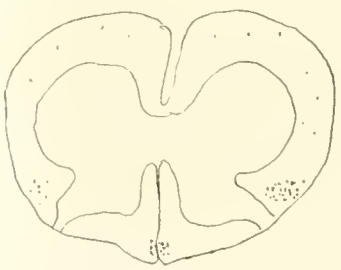

Fig. 8. Second sacral.

form in the posterior columns, and consisted of a few fibers about midway between the commissura and the periphery, and a well-defined bundle lying near the periphery on either side of the posterior fissure. This, however, appeared like the triangular area of Gombault and Philippe.

The fifth lumbar and the sacral portions of the cord exhibited practically the same changes, except that the degeneration in the left lateral pyramidal tract was not so well defined as that in the right.

Examination of sections stained by the Weigert method showed practically the same changes, but also the extensive sclerosis involving the lateral tracts.

The ascending degeneration followed principally the direct cerebellar and Gower's tracts up into the corpora restiforma. The variations in the degenerated area which we found in the different

segments were probably due to errors in technique, but the well-defined changes in the left anterolateral ground bundle could hardly be explained on that ground, and we think the ascending fibers in that bundle had been destroyed by the hemorrhage in the left anterior horn. The fact that the right column of Goll was so extensively involved and not the left, was due without doubt to the hemorrhage occupying the right posterior horn, although it must also, to a certain extent, have involved the column itself, or otherwise we should have found the area following a more radicular course. Instead of this, however, from that level up the degeneration was confined closely to a definite group of fibers into Goll's column.

Comparing the anterolateral and posterolateral tracts, we found that those of the left side in their entire course showed greater involvement than on the right, the explanation of which must lie in the fact that the hemorrhage in the left ventral horn occupied a considerable portion of the base of the posterior horn, and thus interfered with the fibers from which these tracts are derived. That both anterolateral halves showed symmetrical involvement at the level of the ninth dorsal segment, in no way disproved this assumption, since it was quite possible that while the myeline sheaths were destroyed, the axons of a considerable number of fibers might not have been permanently cut off, and hence the fiber resumed its natural appearance higher up, where it was relieved from the pressure of the extravasated blood. In connection with this we should like to remark, although it is perhaps quite unnecessary, that the idea of transmission of pain and temperature sense through these tracts seems unfounded, in view of the retention of both these senses in this case.

The descending degenerations in the posterior columns were too vague and ill-defined to throw much light on that subject; in fact, the findings were rather negative. It would appear, however, that this would support the contention for the exogenous origin of these tracts, since such an extensive lesion of the right posterior horn would give us the right to expect positive topographical evidences in these tracts, if they had their origin in post-horn cells.

Again, we cannot assume that the small portion corresponding to the triangular area of Gombault and Philippe supports the latter, since we had a well-defined degeneration in Goll's column at its dorsomedial margin.

Spinal arterial sclerosis is a condition that permits of being diagnosticated with considerable readiness, especially if there are symptoms, subjective or objective, pointing to generalized arterial sclerosis. As an example of this we may quote the following case:

Mr. W., a salesman forty-nine years old, came to the clinic complaining of general weakness and "nervousness," particularly in the legs. He says that if he walks a short distance he feels this weakness and so-called nervousness coming on in the legs. In addition, he has had for the past month or more a burning sensation in the epigastric region, which is unaffected by taking food. Latterly he has had a great deal of difficulty in holding the urine, a tendency to incontinence. The bowels are constipated. There has been no change in speech, and according to the patient, no mental deterioration except that he has had periods of melancholia. His eyesight has not been good since he was a child; the right eye being weaker than the left. Nine years ago this patient complained of similar symptoms, which came on after an attack of grippe. He was treated in the clinic and recovered in about six months.

He is a fairly well-nourished man of medium build, rather pale and anæmic. His gait shows enfeeblement but no spasticity.

Examination shows a moderate sclerosis of the peripheral blood-vessels, the radials and temporals being distinctly palpable. Blood pressure with the Rivi Rocci apparatus, 185 (normal 135); pulse rate after sitting, 91. The strength of the lower extremities is perceptibly diminished. Although he is able to stand on either foot, his station is unsteady and he cannot maintain it long. He is unable to stand on the toe of either foot. The quadriceps extensor group is much weakened. There is some diminution of the deep muscular sensibility. He interprets passive movements of his joints, but slight movements he finds difficult to localize. This is also true of the position sense when he attempts to simulate the position of one leg with the other. There are no cutaneous sensory disturbances. The tendon jerks are all lively, but there is no Babinski phenomenon. Pupils normal and there is no facial rumor. The blood count shows nearly 5,000,000 erythrocytes and a relatively normal number of leucocytes.

This patient, who is still under observation, has made great improvement while taking small doses of nitroglycerin and iodide, and availing himself of rest, warm baths, and massage.

There is scarcely any department of neurology that stands more in need of reconstruction than that which is now described under the name myelitis, acute and chronic. When the term encephalitis is used, a well-defined clinical and pathological picture is suggested. On the other hand, under myelitis are included, undoubtedly, many cases of spinal arteriosclerosis, disseminated sclerosis, and obliterating endarteritis. We believe that these can and should be distinguished.

THE TREATMENT OF TUBERCULOSIS OF THE LARYNX AND OF THE PROSTATE GLAND BY THE X-RAY, HIGH-FREQUENCY CURRENTS, AND THE COOPER-HEWITT LIGHT.*

DEMONSTRATION OF SPECIAL APPARATUS AND OF A RAPID METHOD OF SKIAGRAPHY.

By SINCLAIR TOUSEY, A.M., M.D.,
NEW YORK.
SURGEON TO ST. BARTHOLOMEW'S CLINIC.

In presenting the subject, the Treatment of Tuberculosis of the Larynx and Prostate by the *X*-ray, High-frequency Currents, and the Cooper-Hewitt Light, it may be best to first give a brief résumé of the literature which has been found bearing upon it.

I have not been able to find anything upon the subject of this sort of treatment for tuberculosis of the prostate gland.

In regard to the treatment of tuberculosis of the larynx by the *x*-ray, Williams, in his excellent work on "The Rontgen Rays in Medicine and Surgery," as aid to diagnosis and as a therapeutic agent, says: "The successful treatment of lupus by the *x*-rays should lead us to try them in laryngeal tuberculosis." And Revillet, as long ago as 1897, reported a case of acute pulmonary and laryngeal tuberculosis treated by the Röntgen rays. Both lungs and the larynx of the patient were affected. The case was hopeless before treatment was instituted, and the patient died. Some good effects, however, were noted. Sleep was improved, temperature became normal;

*Read at a meeting of the Medical Association of the Greater City of New York, April 11, 1904.

there was marked diminution and finally disappearance of dysphagia. In the excellent book of Pusey and Cauldwell upon the Röntgen Rays in Therapeutics and Diagnosis, the above case of Revillet's is referred to and the statement is made that "the use of the rays in tuberculosis of the larynx is being tried quite extensively, there is reason to believe, but nothing definite upon the subject has yet been reported; . . . there is enough ground for hoping for some benefit to justify a thorough trial of the method, since cases are otherwise so difficult of relief." He thinks "it ought to be used as auxiliary to other treatment."

In the same book is figured an *x*-ray tube for the treatment of the larynx. It has a cylindrical prolongation, through which the cathodal stream is directed by the concave mirror to the anode, which is placed at an angle of forty-five degrees near the top of the prolongation. The tube is intended to be introduced into the mouth, and when in operation the *x*-ray is thrown down into the larynx just as ordinary light is directed by a laryngoscope. My own method of application will be given later.

This is all the literature that I have been able to find upon the subjects of *x*-ray in tuberculosis of the larynx and prostate, and the use of high-frequency currents for precisely these conditions does not appear to have been reported.

Treatment of tuberculosis of the larynx by the violet and the ultra-violet rays, as produced by the electric arc light in its various forms, has been employed by our fellow-member, Dr. Freudenthal. From his reports of a number of cases of tuberculosis of the throat, most of them showed extensive lung lesions. In every case there was marked relief of pain and dysphagia, but in no case was there any perceptible effect upon the tuberculous infiltration or ulceration. He says that "although by far the majority of his patients liked the treatment and asked for it, he can see in the electric light only an adjuvant to the host of other remedies at our disposal—an adjuvant that is of great assistance to us in the management of some cases of tuberculosis." This, however, does not refer to the *x*-ray.

The literature of *x*-ray treatment for tuberculosis in general is quite abundant, and may be summarized as follows: There is no doubt at all about its curative effects upon lupus, and many observers have reported successful results in tuberculous sinuses of bone, and in tuberculous glands. I can corroborate this from my own experience.

In regard to pulmonary tuberculosis, I cannot do better than give a digest of the literature just as I find it·

Stubbert (*New York Journal of Medicine*, March, 1902) gives an extended description of the diagnosis of pulmonary tuberculosis by means of the *x*-ray, and alludes without comment to experiments now in use as to the results of *x*-ray illumination upon intracorporal tuberculosis, and says the value of this agent in lupus or extra-corporal tuberculosis is an established fact.

Rudis-Jicinski (*New York Medical Journal*, March, 1901) reports laboratory experiments in regard to bactericidal effects of the *x*-ray upon tubercle bacilli, as well as upon other pathogenic microorganisms, and shows in general that tubercle bacilli in an alkaline medium are not destroyed by the *x*-ray, but that in 40 per cent. of the animals inoculated with tubercle bacilli whose secretions were kept acid, a cure of a beginning tuberculosis was produced, and this was verified by autopsy five years later. Giant cells were not found, but there were chalky masses enclosed in dense tissue, connective tissue, and adhesions, but no tubercle bacilli. He reports twenty selected cases of human pulmonary tuberculosis at an early stage treated with the *x*-ray in one year. One died of intestinal tuberculosis; another committed suicide after two sittings; four proved complete failures, and the rest were doing comparatively well at the end of the year.

Ransom (MEDICAL RECORD, February, 1904) reports seven cases of chronic pulmonary tuberculous phthisis, with very profuse expectoration, treated with marked improvement in quantity and quality of expectoration, and general improvement of symptoms. Still under treatment. Two cases of advanced chronic pulmonary tuberculosis. Treatment was discontinued on account of low condition of patient. Six cases of chronic pulmonary tuberculosis still under treatment and doing well. As a caution, he states that in his experience he has had three slight hemorrhages immediately following exposure, in cases in which hemorrhages had been of recent origin.

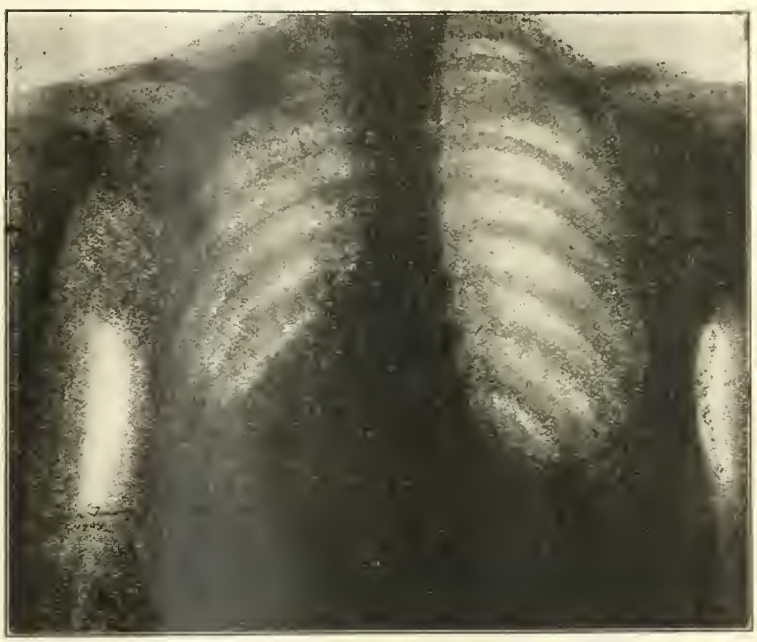

FIG. 1.—Radiograph of the chest. Case of tuberculosis of larynx and lung under treatment by the *x*-ray, high-frequency currents, and the Cooper-Hewitt light.

Freudenthal (MEDICAL RECORD, March, 1904) reports encouraging results from the use of blue light and intrarectal injections of CO_2 gas, for pulmonary tuberculosis.

Bowie (*Lancet*, October, 1903) considers high-frequency currents of low potentiality to have a curative effect in pulmonary tuberculosis. The currents, which are given directly to the walls of the thorax, bring about a stronger power of resistance to the toxins of the tubercle bacillus.

M. F. Coomes, in an article on Tuberculosis (*American Practitioner and News*, September 1, 1903), says that "very little is known of the value of *x*-ray in this affection. The clinical reports of cases up to the present time are not encouraging. In many cases the diagnosis had not been absolutely established, and they are therefore worthless. A few favorable reports have been made, but they are

from people who have also received other treatment. The author subjected one case daily for more than six months to the rays. Patient had a large cavity in upper part of left lung; sputum contained blood, pus, and tubercle bacilli in large numbers. Weight was 150 pounds at the beginning of the treatment. In addition to *x*-ray treatment, the patient received 140 gtts. or more daily of creosote, and the best of food. After six months he weighed 151 lbs. During the treatment he expectorated blood only once."

Hahn (*Fortschritte a. d. Geb. der Roentgenstichler*, Bd. III, H. 1, f. 36). Reports case of pulmonary tuberculosis treated by Reider with *x*-rays; the result was entirely negative.

Bergonie and Mongour (*Archives d'électricité Médicale*, August 15, 1897) report two cases of acute phthisis in very much run-down individuals suffering from insufficient food and alcoholic excesses. The results in both cases were negative. In a more chronic case a slight improvement was obtained. This case showed rapid improvement in general condition and strength, and the appetite increased. The local pulmonary processes, however, were unaltered. A third case, after a month of improvement, both in general condition and locally, had severe digestive disturbances which caused a relapse.

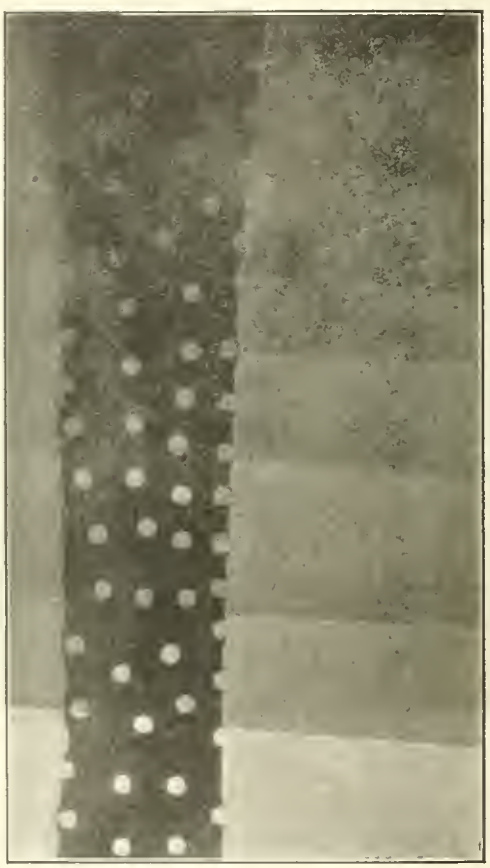

FIG. 2.

FIG. 3.

Radiographs of Dr. Tousey's Radiometer. Both pictures were made by the same *x*-ray tube, using the same strength of current and at the same distance. In figure 2 the vacuum was high, but in figure 3 the vacuum was of the moderate degree, which the author finds to have a curative effect on tuberculosis. Both figures show part of the sheet-lead shielding the hand of the operator.

Bouchard (*Traité de Radiologie Médicale*) says that "the *x*-ray treatment of pulmonary tuberculosis received a very thorough trial by many observers, after Rendu and du Castel observed amelioration of symptoms in a young man suspected of pulmonary tuberculosis. There is not a single confirmed case on record of a cure, and to-day the treatment is almost abandoned. Since the year '98 fewer and fewer new cases are being reported. Many of the publications are premature; after a temporary improvement (so common in tuberculous people from the institution of a new treatment) the disease again progresses unfavorably. Du Castel and Rendu's patient and those of Chanteloube, Descamps, Rouilliés, and Revillet, all died after the publication of their cases. In the greater number of patients no change could be detected. With some, on the contrary, after a temporary improvement, an acute phthisis was set up which carried the patient off in a short time (Roullet, de Tiessiere, and Bergonie, d'Ausset, de Potain, and Serbanesco). This fatality is due to a stimulation of a quiescent lymphatic tuberculosis."

Gilman (*The Clinique*, Vol. 18, 1897) reports a case of an Italian boy twenty-two years old, suffering from an apparently hopeless case of pulmonary phthisis. The right lung from apex to mammary region was merely a cavity, anorexia and insomnia were present. The temperature rose daily to 104° F., hemorrhages occurred every four to six weeks. After the first treatment the temperature was reduced; sleep and appetite improved, strength returned, and hæmoptysis ceased in the course of the treatment. At the end of the treatment the patient was still weak.

Barthélemy and Oudin, cited by Havas (*Archiv für Dermatologie und Syphilis—Kaposi Festschrift*, 1900), say that a latent tuberculosis may become acute through *x*-ray treatment. The authors substantiate this statement by a single observation.

Burdick (*American Electrotherapeutic and X-ray Era*, 1903, No. 3, p. 1) says that "in patients of sufficient recuperative powers, no treatment other than the *x*-ray is required; in more debilitated individuals other forms of treatment must be used to supplement it. A powerful generator is necessary

and tubes at the proper vacuum. If the vacuum is too high, the tuberculous process is hastened. Absolute cures are not accomplished; the pulmonary signs persist, and there is occasional expectoration of sputum containing tubercle bacilli. The *x*-ray stops the growth of the bacilli long enough to enable the vitality of the body to be restored so as to cope with the disease. In incipient cases the recovery is rapid and prompt. Some cases show great reaction in the beginning, requiring the treatment to be stopped." The author reports thirteen cases of pulmonary tuberculosis treated in this way, supplementing a report of sixteen similar cases (*Am. Electro-Therapeutic and X-rayEra*, July, 1901).

Chanteloube, Descamps, and Rouillés (*Archives d'Electricité Médicale*, May, 1897) report the case of a patient twenty-one years old with both lungs affected, numerous bacilli in the sputum, and continuous fever for two months. After the eighth seance, the temperature was markedly lower. The course of the disease was not influenced, there was only an improvement in the general condition. After twenty-one further seances (two being given a day), the cough and expectoration diminished and finally the bacilli disappeared almost entirely. There was still fever, and the general condition remained the same. The good effects produced continued, the cough was less, and an intercurrent diarrhœa disappeared. The physical and psychical conditions improved, but the disease continued, there being always an even temperature of 38.5° C. Following the publication of the report the patient died.

Teissier (*Archives d'Electricité Médicale*, No. 6, 1898) reports the case of a young girl of twenty-one in the second stage of pulmonary tuberculosis, which was progressing slowly, who was given daily treatment with *x*-rays for fifteen days. Bronchopneumonia with bloody expectoration developed. Six weeks after the treatment had been stopped the patient died. A young man with an apyretic tuberculosis in the second stage, having an induration of both apices and tuberculous cervical glands, was given twenty-two seances with frequent intermissions. No change was noticed except a diminution in size of cervical glands.

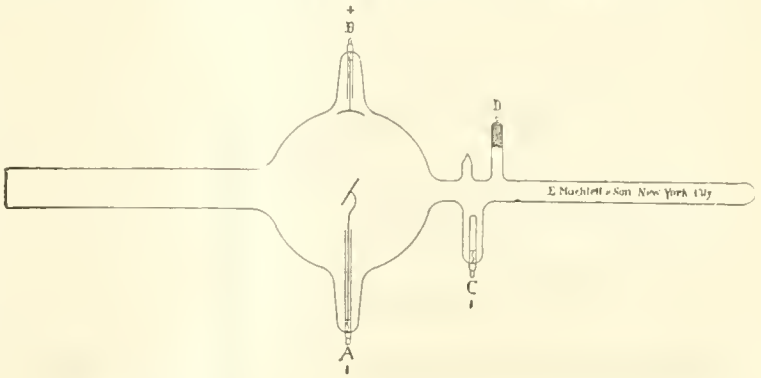

FIG. 5.—Tube used for applying the *x*-ray to the outside of the throat in tuberculosis of the larynx.

FIG. 4.—Radiograph of the hand of a patient under *x*-ray treatment for subacute rheumatism. This shows the degree of vacuum (quality and penetration of light) found by the author to produce a curative effect upon tuberculosis.

Destot and Dubard (Fourth Congress for the Study of Tuberculosis, 1898) attribute the therapeutic effects of the *x*-ray to the electrical radiations which accompany the former. The Crookes tube only acts as a rheostat. In the opinion of the authors, electric radiations obtained from another source are preferable.

Ausset (*Journal de Clinique et de Thérapeutique infantiles*, 1897). A young girl of seven with advanced tuberculosis of both lungs and large mesenteric glands was treated for twenty days. Abdominal pain and diarrhœa ceased. This temporary improvement disappeared as soon as the treatment was discontinued, and the patient died soon after.

Bergonié and Mongour, in an article entitled "Have the *X*-rays Any Action in Human Tuberculosis?" (*Bulletin de l'Academie de Médecine*, 13, VII, '97), say that a diminution in the number of tubercle bacilli did not occur. There is probably, they think, no specific action against the bacteria—perhaps phagocytosis is favored.

Sinapius (Die Heilung der Lungentuberculose durch Röntgen Bestrahlung, Leipzig, 1897). Although good results are claimed by him in a number of cases, the reports are not considered of value as the diagnosis of tuberculosis had not been established beyond doubt.

My own opinion at the present time is that judicious application of the *x*-ray or of the ultraviolet ray and high-frequency currents is indicated in every case of tuberculosis.

I wish now to report the progress made so far in a case under treatment for tuberculosis of the larynx. The patient, Mrs. V., was referred to me by Dr. Roof. She had been running a temperature of 102°, had had throat trouble for three years, and during the last few months profuse expectoration, and a tuberculous deposit visible in the larynx. The expectoration had been so profuse as to choke her and was full of tubercle bacilli. Weight 103, the maximum having been 130 pounds. One feature of the case had

been a feeling on the part of the patient that she could not swallow anything solid, and for some months she had taken nothing but fluids strained through fine cloth. At the start she was constantly coughing and expectorating, could hardly speak above a whisper. There was considerable loss of strength and there was but little evidence of pulmonary trouble. The skiagraph of her chest (Fig. 1)

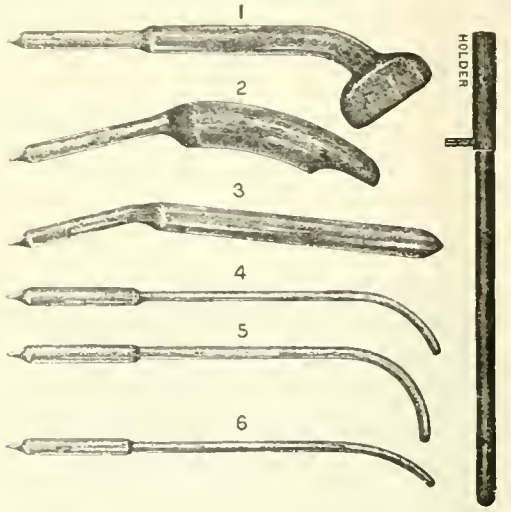

Fig. 6. Vacuum electrodes and handle for applying high-frequency currents to the surface of the neck and chest; used in cases of tuberculosis of the larynx and lungs.

was taken shortly after the commencement of treatment, and shows the right side of the chest more transparent than the left, and some cloudiness at the left apex. It is a beautiful picture from a surgical point of view, as it shows the relations about the shoulders so well, the entire outline of the scapula, the ribs showing through the scapula and the clavicles through the entire thickness of the chest. My treatment was begun on December 15, 1903, and consisted in, first, the exposure to the *x*-ray once every four or five days; exposure to the Cooper-Hewitt light and application of high-frequency currents once in each interval between the *x*-ray application;—so that on Tuesday she would be treated with the *x*-ray, on Thursday with the Cooper-Hewitt light and high-frequency currents, on Saturday with the *x*-ray, and on the following Tuesday with the Cooper-Hewitt light and high-frequency currents, etc. In applying the *x*-ray, I used an 8-inch Wappler coil, run by the current from the street (110 volts direct current), using a liquid interrupter. This consists of a beaker of tough porcelain with three or four pinholes near the bottom; this is set in a large jar full of dilute sulphuric acid, and a lead plate connected with one wire dips into the acid outside, while a lead ring from the other wire dips into the acid outside of the beaker. When the current is turned on, electrolysis takes place in the dilute acid through which the current has to pass, and the resulting bubbles of hydrogen and oxygen gas block up the pin-holes and interrupt the current. The current ceasing, the bubbles of gas escape and the current recommences. In this way the current through the primary coil is interrupted surely, safely, and almost noiselessly, at the rate of about ten thousand times a minute, and each such current passing through the primary coil induces a current of very high voltage in the secondary coil. From the two poles of the secondary coil wires pass to the two poles of the *x*-ray tube, the negative terminating in a concave mirror, the cathode, within the tube, and

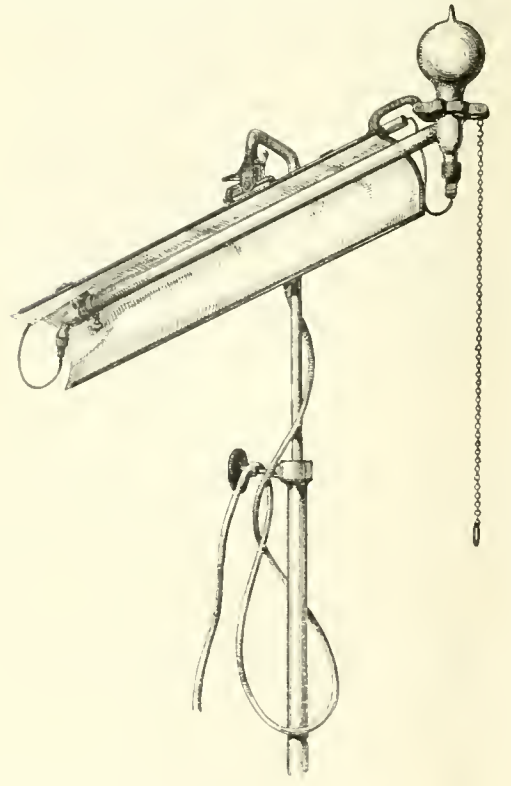

Fig. 7.—Cooper Hewitt Lamp.

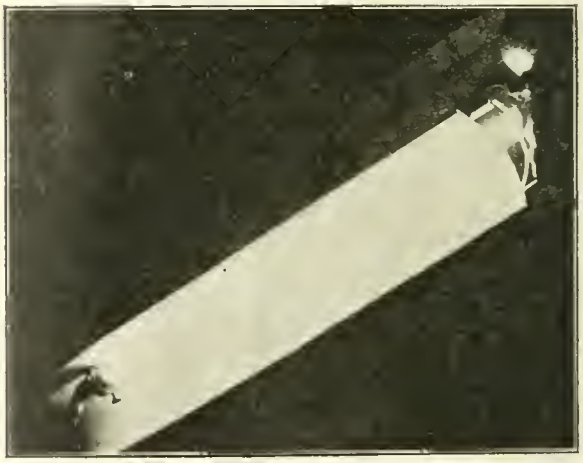

Fig. 8.—Cooper-Hewitt light in operation.

the positive wire terminating in a platinum disk, the anode, in the center of the tube. When in operation, a very fierce bombardment of molecules passes from the cathodal concave mirror to an exact focus on the anode, where they are taken up in the new form of motion called the *x*-ray. In treating this case two different tubes were used—First, a Gundlach heavy anode tube of 60 cm. capacity; and later, a Müller heavy anode tube of 50 cm. capacity. Both were provided with regulating devices, and the degree of vacuum was so adjusted as to give the greatest photochemical effect which can be combined with sufficient penetration to pass through the entire thickness of the chest. The chest picture which is shown was taken in the course of the treatment—simply placing a plate behind the chest during exposure to the *x*-ray. To be more specific, the internal resistance of the tube was reduced to that of a 2½ spark gap, and the penetration of the light as shown by the author's radiometer, was sufficient to shine through three thicknesses of tin foil, of which 100 square inches weigh an ounce; both of these conditions being combined with a strength of current sufficient to produce a six and three-quarter inch spark. Four and a half amperes of 110 volts pass through the primary coil. The picture of a hand of another patient, showing the condition after radiotherapy for subacute articular rheumatism (Fig. 4) was taken with a tube

regulated in this way. The distance from the nearest surface of the chest to the anode was about ten inches, and the time of exposure about five minutes in front and five minutes behind. The face and scalp were shielded by a sort of cap of *x*-ray metal (sheet lead with a sufficient alloy of tin to prevent it from rubbing off on the hands and face.)

Following the general exposure of the chest to the *x*-ray, a special application was made to the larynx by means of the *x*-ray tube which I show here. The

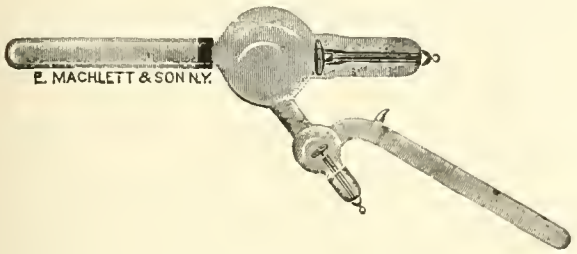

Fig. 9.—Tube used for applying the *x*-ray inside of the rectum in tuberculosis of the prostate.

major part of the tube is made of a lead-glass opaque to the *x*-ray, except for a cylindrical prolongation into which the rays are directed from the anode and from the transparent end of which they emerge. This is held close to the outside of the larynx, and directs the rays through the exact tissue which we wish to influence, and requires no shield of any kind. The names of Cauldwell and Morton in this country, and of Cossar in Europe, have been associated with this type of tube, in which some trifling modifications have been made for my own purposes. The current employed is milder and the exposure only about three minutes, and this is distributed over different aspects of the larynx.

The high-frequency currents are obtained from the same eight-inch *x*-ray coil by means of the D'Arsonval transformer. This consists of two large Leyden jars, each of which contains a pint or two of salt solution, forming the inner coating. The outer coatings are of sheet metal and are connected by a spiral of wire forming a solenoid, and from the two ends of this insulated wires pass to the patient. One of these wires terminates in a metallic handle, which is held by patient; the other, in an insulated handle in which fits a vacuum tube with a flattened bulbous extremity, which is applied to all the different parts of the chest and the outside of the throat. When in operation, a series of sparks passes across a spark-gap enclosed in a glass cylinder between the tops of the brass rods which pass into the inside of the Leyden jars and which are connected with the two poles of the *x*-ray coil; and the vacuum electrode becomes filled with ten thousand waves a minute of ultraviolet and violet light passing into the surface of the body. A very large amount of ozone is also generated and carried into the body by the electric current, which is an important feature of the application. The patient actually receives all the way up to one hundred and twenty-five milliamperes. This is quite devoid of any shock or of the unpleasant sensation of Faradic electricity. The intensity of the application is controlled by regulating the current in the *x*-ray coil and the length of the spark-gap in the D'Arsonval. The proper strength seems to be one devoid of prickling sensation, but strong enough to warm up the vacuum bulb where it is in contact with the skin. These vacuum electrodes contain no wires. The current is simply intense enough to penetrate the glass at the top, pass through six or eight inches of a partial vacuum, and penetrate the glass again where it is in contact with the body.

The Cooper-Hewitt lamp is actuated by the street current reduced by a rheostat to five amperes with 110 volts; this current passes through a vacuum tube twenty-four inches long and one inch in diameter, and containing vapor of mercury and at one end a certain amount of liquid mercury. To start the lamp the current is turned on and the tube tipped so that the liquid mercury will form a complete connection between the platinum wires entering the ends of the tube. After the current is once started through the tube in this way, the tube is allowed to assume its normal position with the liquid mercury all in the reservoir at one end and the vapor of mercury continuing to transmit the current becomes incandescent. The light given out has four hundred candle power, its spectrum is almost pure violet—that is, it contains the chemical and life-giving properties of sunlight about a hundred times intensified, for it can be placed within four inches of the bare chest without danger of burning. In my apparatus the light can be adjusted at any height, and a reflector shields the patient's face and eyes. This light is applied almost fifteen minutes in front and almost fifteen minutes behind the chest from a distance of about five or six inches.

The result of treatment has been the disappearance of expectoration, and this took place in three weeks; very great improvement as to the voice—for instance, now she talks over the telephone perfectly well—marked gain in strength; her temperature is normal; and a gain in her average weight of about two pounds. The local condition was examined by Dr. Richard Kalish before treatment, and again a few days ago. Originally he found an area of swelling and hyperæmia below the left ventricular band with a distinct line of abrasion, though scarcely ulceration, there. Now he finds the area of infiltration diminished and the abrasion healed, with a whitish appearance which may be due to cicatricial tissue. Considerable improvement has taken place in regard to swallowing, the difficulty in regard to which has appeared to be entirely psychic from the start. Physical examination of the chest shows slight dulness at the left apex, scarcely any perceptible abnormality at the right apex, and slight dulness below the angle of the left scapula, which may be due to a slight central consolidation or to a spot of pleurisy. The patient is still under treatment.

In the treatment of tuberculosis of the prostate and bladder, my treatment has consisted in allowing the light from an ordinary *x*-ray tube, regulated as described above, to shine obliquely downward through the lower portion of the abdomen and also occasionally through the perineum. This application lasts about five minutes. Alternating with the perineal application, a special *x*-ray tube has been introduced into the rectum. This tube is made for the most part of lead glass, which is opaque

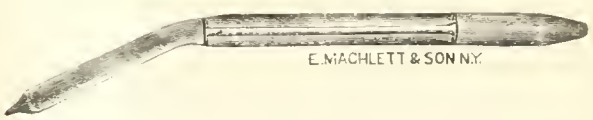

Fig. 10.—Vacuum electrode with insulated shaft for the application of high-frequency currents in the rectum; used in cases of tuberculosis of the prostate.

to the *x-ray*. It has no anodal disk; its cathode stream is directed down a cylindrical prolongation of transparent glass from which the *x*-ray emerges in all directions. This prolongation is cooled by a continuous current passing through a water-jacket, and the application lasts only a couple of minutes. The other portion of the treatment consists in the application of high-frequency currents over the lower portion of the abdomen; and in the rectum on occasions when the intrarectal *x*-ray tube is not used. For the intrarectal applications of high-frequency currents a special vacuum elec-

trode is employed in which the tube is insulated except for its distal two or three inches by a separate external cylinder of glass. In this way all the effect reaches the interior of the rectum. The application lasts five minutes.

The patient upon whose case I wish to make a preliminary report is Mr. M., aged thirty-one, who has suffered for several years from tuberculosis of the bladder and prostrate. He was treated with the *x*-ray a year ago by an excellent man, the application being made daily by allowing the light to shine upon the lower part of the abdomen while the patient stood up in front of the tube, also by the application of vacuum electrodes connected directly with the *x*-ray coil without the D'Arsonval transformer. For about a year and a half before this treatment was begun several enormous pus sacs had been gradually forming, and for almost all that year and a half he had been unable to lie upon his back because of the pain. After the *x*-ray treatment had been applied for several weeks these emptied into the bladder, and at one time he passed a quart of pus in forty-eight hours. At that time he was urinating about a hundred times a day. When he came to me, December 23, 1903, his weight was 147 pounds, he was urinating twenty-five or thirty times a day. Rectal examination showed the prostate to be moderately enlarged and tender. The urine looked like a mixture of blood and pus, and the microscopical examination showed the presence of tubercle bacilli. He has been treated twice a week, and the abdomen and perineum are somewhat tanned from exposure to the rays. Irrigations of various kinds have been continued. There was at first considerable pain and irritation in the urethra, and scales could be washed out of it. This has been relieved by *x*-ray applications, the penis being held up against the abdomen during the *x*-ray treatment. His weight now is 152 pounds, his strength is very much greater, the urine is a great deal clearer, and no visible blood has been present in it during the last two months. The microscopical examinations which have been made at Fraser's laboratory each month showed at first an increasing and lately a rapidly decreasing number of tubercle bacilli. The examination made a day or two ago shows "only an occasional tubercle bacillus."

On several occasions lately when calling on friends he has gone five hours without urinating, without discomfort; previously he always had to consider ways and means of urinating several times during any such period as that. During the present course of treatment there has been no formation of pus sacs, and the comfort and strength of the patient have uninterruptedly improved.

103 West Seventy-sixth Street.

Alcoholism in Normandy.—It is stated that the population of the five departments of Normandy is 150,000 less than it was thirty years ago and the decrease is attributed in great measure to the excessive use of alcohol. M. Debove, the dean of the Paris Faculty of Medicine, shows how alcohol operates in two directions toward the diminution of the population—by raising the average of mortality and by weakening the vitality of the majority that survive. There are places in Normandy where the consumption of brandy is more than a quart per day per head of the adult population. Alcoholism is said to have got a firm hold on a large part of the female population. In the "fairly temperate" canton of Tourouve the average weekly consumption of raw spirits is a little over three and a half quarts for each male adult and about two quarts for grown up women and young children.

INTERNAL URETHROTOMY IN THE TREATMENT OF STRICTURE OF THE MEMBRANOUS URETHRA.

By CHARLES C. MILLER, M.D.,
CHICAGO.

It is usually maintained by surgeons that it is better to treat strictures of the membranous urethra by gradual dilatation than by internal division, and in this article I wish to point out briefly some of the more important reasons for preferring division of such strictures to dilatation, and the precautions which are necessary in performing this operation in order that the results may justify the course.

When extremists advocated internal urethrotomy with undue enthusiasm years ago, it resulted in the development of other extremists who were partisans of the treatment by gradual dilatation, and while the extremists for urethrotomy were proclaiming with exaggerated zeal the virtues of extensive division of strictures, the partisans of dilatation were formulating and propounding even more radical and fully as unjustifiable claims for gradual dilatation.

Many men are blind followers of the gospel of the literature, and at this time the man who was in favor of urethrotomy felt that it was necessary for him to also be in favor of the prevailing vogue of extensive and free division of strictures. Strictures were cut from thirty-six to forty-five French, and while such a plan could be followed with comparative safety in the antescrotal urethra, such divisions in the perineal urethra were followed by free hemorrhage and painful erections in a percentage of cases rather larger than could be desired. Instead of reducing the scale of division of such strictures to within reasonable limits, operators in most instances either conceded that internal operations should here give way to the external section of the urethra or that gradual dilatation be practised. A few capable men with more logic than is usually conceded them held out for divulsion in these cases.

Gradual dilatation is in a great majority of instances a safe and satisfactory method of treating strictures of the urethra, when anterior to the penoscrotal juncture, but the same cannot be said of this treatment for a large proportion of strictures posterior to this point. The reasons for this are clear.

In all strictures of the urethra we have a chronic inflammation and irritation of the mucosa over the stricture and posterior to it. This inflammation, we know, is due to a chronic persisting infection at this point, probably made possible by the increased friction and irritation of the urinary stream.

We have in all cases of stricture of any considerable degree more or less residual urine in the bladder after urination. This can be demonstrated easily by an observer. It will be found to be particularly true in cases of stricture of the perineal urethra. Residual urine which cannot be expelled voluntarily, will alter greatly the character of the bladder from the standpoint of the surgeon, for such a bladder retaining urine after each urination will no longer be a self-draining organ, and as a result infection is much more easily developed, and overcome only with greater difficulty than in the normal bladder.

Careful aseptic precautions should always be taken in practising gradual dilatation if satisfactory results are to be hoped for, yet excluding all external sources of infection, it is still possible to have an acute inflammation develop, as the result of bacterial proliferation. In other words, a sterile sound by its mechanical irritation can favor conditions which will permit of the proliferation of the germs already present in the chronically inflamed mucosa about the site of the stricture. In the patient with stricture in the urethra anterior to the scrotum it is unnecessary

to carry the instruments used in the dilatation into the bladder and as a result the irritation is confined to the urethra, and increased infection, as a rule, is limited to this organ. When the stricture is of the perineal urethra, to insure dilatation of the stricture, the instruments are carried into the prostate and bladder. The bladder may be more or less infected, and the trauma, coupled with the spread of infection from the urethra into such a bladder, makes the development of acute cystitis not infrequent. In these cases we are also liable to have develop, at any time during the treatment, an acute inflammation of the prostate, seminal vesicles, or epididymis.

In all cases of intraurethral instrumentation, we may have develop a form of chronic infection, which is very likely to escape the attention of one, who is dilating a stricture, and yet which may result in no little mischief to the patient.

A patient is examined for stricture and such a lesion is found, and gradual dilatation is instituted in the treatment of the lesion. All aseptic precautions may be taken, and the patient be regularly taking internally urinary antiseptics. Nothing peculiar is noted in the dilatation, except, perhaps, a rather irritable urethra. This patient attends to his business, but as he continues the treatment, you notice, that his face becomes somewhat drawn and haggard, his color becomes somewhat pasty; he may notice some loss of flesh; his tongue is coated and he feels more or less lethargic. If this patient's temperature be taken at frequent intervals following the sounding it would be found above the normal at some time during the twenty-four hours. These forms of infection are not to be ignored, and if they cannot be overcome, the best possible course will be an internal urethrotomy, after due preparation.

The greatest disadvantage of gradual dilatation is the difficulty of holding patients until a caliber has been reached in the dilatation which will make the stricture no longer a menace to them.

If a patient come with a stricture of ten or twelve French and treatment by dilatation be instituted, that patient will almost certainly discontinue treatment before a caliber of twenty-five French has been reached. The reason for this is plain: The treatment will extend over a period of a number of months in most instances, and there is an irksomeness to the treatment which the patient dislikes. He begins to fear the size of the instruments; and all symptoms often disappear except the shreds in the urine. The urinary stream becomes free and satisfactory to him by the time fifteen or eighteen French has been reached. The patient has only the unsupported statement of the surgeon, that the dilatation should be carried up to a size, which appears to him extreme, so that in a great majority of instances gradual dilatation is never completed where a stricture is below fifteen French. Patients with strictures above twenty French and above fifteen where they dilate readily may often be quickly carried up to the full normal caliber, and then be held for sounding every two or four weeks for a considerable time.

In a rather large percentage of cases of stricture of the perineal urethra an examination per rectum will reveal an infected prostate or infected seminal vesicles, and in all such cases internal urethrotomy is indicated, followed by a minimal intraurethral after-treatment.

These patients with the chronic infection of the prostate and vesicles consult suffering from the various neurasthenic symptoms, which manifest themselves in chronic infections of these organs, and an attempt at treatment by gradual dilatation of a stricture of the perineal urethra will be followed by an increase in the inflammatory condition, and as a result the patient will be made worse by the treatment, at least so far as his observations are concerned. In my own experience, I have found it impossible in many instances and too troublesome in the remainder of cases to attempt to hold such cases while treating by gradual dilatation, and therefore submit all such cases to internal urethrotomy.

The operation is done in these cases after very careful preparation, and the after-treatment is minimized in order that the reaction may be as slight as possible. Treatment by massage is instituted as soon as no bleeding occurs during urination or after sounding. When the condition in the vesicles has been decidedly improved, and not until then at least is any considerable intraurethral treatment or manipulations instituted.

When we decide upon internal urethrotomy as an elective operation in the treatment of stricture of the perineal urethra, certain precautions should be taken in the preparation of the patient, in the performance of the operation, and in the after-treatment.

The operation should not be performed as an elective operation in any case, if there is an acute inflammation of any portion of the genitourinary tract. This condition will manifest itself not infrequently by the presence of a considerable amount of pus in the urine. Such should be overcome, and the urine should contain only a few shreds at the time of operation.

The free use of urinary antiseptics is of an advantage. For a long time such agents as boric acid and salol were depended upon in these cases for their antiseptic effect, but of late years certain special urinary antiseptics have come into general favor as superior to these former drugs. I use both types of drugs, the latter agents about the time of operation, the former some time before and some time after the operation. In other words, in clearing a urine of pus a half drachm of boric acid and an equal amount of salol daily may prove very valuable, but beginning three days before an operation and for the same time after operation full doses of the special urinary antiseptics are used. The use of the urinary antiseptics is of secondary importance to the local aseptic and antiseptic precautions.

The patient should be prepared before the operation by a thorough scrubbing of the genital region, and it is well to shave away the pubic hair. The bowels should be emptied by salines or injections, and the same precautions taken in preparation as in all operations requiring a general anæsthetic.

Internal division can be accomplished under local anæsthesia, but it is an unpleasant experience for the patient, and the operation is almost always performed in a hasty and imperfect manner under those circumstances. One can seldom tell when he will meet with a patient who will become extremely nervous as the work progresses, and such a patient is in more danger of doing himself harm than is desirable, so that the risk of a general anæsthetic is more than counterbalanced by a more complete and satisfactory operation.

Everything about the field of operation should be protected by sterile sheets and towels, and the operator should wear a sterile gown and cap. The hands of the operator should be prepared as carefully as though an intraabdominal operation was to be performed, and the instruments should be carefully sterilized by boiling.

The urethra should be irrigated with a one to five thousand solution of formalin, and if the bladder can

be reached with a small catheter it may be washed out.

The popular urethrotome in this country is that of Otis, a modification of which instrument has been devised for operations upon strictures in the perineum. I do not like this instrument for this purpose in most strictures. Before the Otis instrument can be introduced the caliber of the urethra must be about fifteen or seventeen French. If smaller, a long filiform must be threaded through the stricture, and then the Otis threaded upon the filiform and the two carried into the bladder. Now the Otis has a blunt extremity, which when carried through a stricture by force guided by a filiform, more or less laceration of the urethra transversely is likely to occur. This disadvantage is not to be met with when the Maisonneurve urethrotome is used. This instrument, as made at the present day, consists of a small staff about seven French in its greatest diameter. This staff tapers to a woven filiform, which is attached to the staff by a small screw attachment. A channel along the staff guides the knife of the instrument. This knife is triangular, and has a blunt tip which lifts the healthy urethra away from the cutting surface of the blade. It is passed along the groove from the meatus to the bladder after the instrument has been introduced. The knife thus divides any obstruction which it meets in its passage.

The technique of the operation with the Maisonneurve is simple. The filiform is anointed with a sterile lubricant and is passed through the stricture into the bladder. If the stricture is very small in caliber the filiform can be passed before the anæsthetic is given. The operator then screws the staff of the instrument to the filiform, and it is then carried into the bladder just as one would a steel sound. The filiform safely guides the staff into the bladder, and where the stricture resists it can be gently forced by the staff. The filiform coils up in the bladder. The staff is steadied by an assistant, and the knife selected can be passed along the groove into the bladder. The knife can now be withdrawn or the whole instrument can be withdrawn, as the operator elects.

Blades of various sizes are supplied with the Maisonneurve instrument; the largest should cut to thirty-two French. The efficient division of the stricture can be demonstrated by the passage of a sound of this size as a concluding step to the operation. The Otis instrument would permit of a much more free division of the strictures, as its scale runs to fourty-five French, but such free cutting internally is not to be recommended in the membranous urethra.

The operation should be completed by a hot antiseptic irrigation of the urethra and bladder. A special staff is supplied with the Maisonneurve instrument to allow of the passage of a catheter over it, but it is seldom necessary. An ordinary catheter can, as a rule, be passed without difficulty.

No catheter should be retained in the bladder or urethra after the operation, such are not only useless, but harmful. The patient should be put to bed and kept quiet until the bleeding has ceased. This in most instances amounts to less than a drachm. Sometimes the patient will have an oozing for ten or fifteen minutes. It is but seldom that measures need be taken to control the bleeding.

An operator should always be acquainted with the various means of controlling hemorrhage from the urethra, if he contemplates an internal urethrotomy. He will seldom have use for his knowledge.

In these cases of stricture of the perineal urethra we have none too perfect drainage after the internal operation and so we cannot use certain hæmostatic agents with impunity. If we wish to control a bleeding, we have those drugs which act upon the blood and those which act upon the vessels. The agent which acts upon the blood to control bleeding does so by causing a rapid, firm clotting of the blood. Such agents should never be used in the control of bleeding of the perineal urethra, as they form firm adherent clots, which clots, decomposing, favor the development of bacteria. If they are washed away, as I shall describe later, the bleeding will recommence.

Agents which act upon the vessel walls are not to be condemned if sterile, but as a rule they will prove inefficient, in that form of hemorrhage which needs attention. If an operator is foolish enough to become excited and inject hæmostatics into every urethra after the bleeding has persisted for five minutes, he will soon have many cases in which he has secured wonderful effects from some hæmostatic, but if he waits a reasonable time before beginning his efforts to control the bleeding, he will seldom have use for methods to control bleeding.

The agents, which act upon the vessel walls, are not likely to control a persistent bleeding, as such does not come from a large vessel so much as from a number of vessels which are implicated in the cicatricial tissue of the stricture, and which cannot as a result retract and contract.

A very moderate pressure upon the perineum will control a bleeding after internal urethrotomy, if such is properly applied. Internal pressure will not be tolerated. I have tried the passage of a soft rubber catheter in these cases, but the discomfort caused by its presence is too great to make it useful for hæmostasis.

Pressure is best applied to the perineum by the use of a padded pole or splint, after the method described by Otis. A large pad is made with cotton and a bandage over the end of a board or splint which is long enough to reach from the footboard of the bed to the perineum. The patient is pulled down upon the pad, and in this way constant moderate pressure is exerted upon the whole perineum. A large pad, which fills the interval between the legs, will exercise pressure upon the proper point and is better than a small pad, as the latter must be placed so as to exercise pressure upon the right point, and when the patient falls asleep it is very likely to become displaced. The patient should be given a small dose of morphine, and a nurse should be instructed to watch and see that no bleeding occurs during sleep.

The blood escapes from the meatus in these cases, and when under control such can be seen by an inspection of the penis. The patient can relax the pressure every hour, and when the bleeding has ceased he can permit the pressure to remain off.

The most important feature in the care of the patient after the division of strictures in the perineal urethra is to prevent as much as possible constitutional reaction. This will follow a majority of internal urethrotomies, no matter how carefully they have been performed. It will seldom be dangerous, but should never be neglected.

The patient feels perfectly well after the internal urethrotomy, but if his temperature is taken every few hours, within twenty-four or thirty-six hours there is usually a rise of one or two degrees. With it the patient may feel ill, may vomit, or at least suffer a loss of appetite, considerable lassitude, and sometimes become quite alarmed at the various symptoms which have developed.

This reaction is due to imperfect drainage, and can be overcome with ease by an antiseptic urethral irri-

gation. The instruction left after urethrotomy should be for an irrigation of a one to seven thousand formalin solution hot, as soon as the temperature goes above one hundred. This is to be repeated every four or eight hours until the temperature is normal and remains so for at least eight hours. Then the irrigations may be used twice daily during the first week following the operation.

The irrigations with formalin solution, when no stronger than one to five thousand solution, are not unpleasant, and the patient enjoys their use rather than otherwise. A glass tip is used with the irrigator, and the stream is allowed to flow into the meatus and out again, and it will make its way back to the point of section, and thoroughly cleanse this area. The value of the irrigations is demonstrated by the prompt fall of the temperature after their use.

Much has been said regarding the after-treatment of strictures, which have been treated by internal urethrotomy. For my own part I believe that operators have been conceding entirely too much importance to sounding after this operation, and especially after the internal division of strictures in the membranous urethra.

The urinary stream as it emerges from the bladder passes into the large prostatic urethra. From here it enters the smaller membranous urethra, and after an internal urethrotomy the stream plays a very important part in preventing any reunion of the divided ends of the stricture. I have had no reason offered which encourages me to use the sound every day or two after this operation, and have had only the best of results following rather infrequent sounding. I sound patients for the first time from five to seven days after the operation, and then for six weeks at intervals of from five to seven days. I have examined a number of patients from one to two years after this operation, when intervals of months have elapsed after the last sounding, and have had no difficulty in passing a full-sized instrument into their bladder.

In my clinical work during the last eighteen months I have had several patients who refused to permit any sounding immediately after the operation, being satisfied that they had a free stream and these patients, returning, have consented to sounding from two to six months after the operation, and a full-sized instrument has been passed without resistance.

ALCOHOLISM AND INEBRIETY: AN ETIOLOGICAL STUDY.

By T. D. CROTHERS, M.D.,
HARTFORD, CONN.
SUPERINTENDENT, WALNUT LODGE HOSPITAL.

Some leading physicians have affirmed with emphasis that alcoholism and inebriety are the same, and that the attempt to dignify them by the term "disease" is absurd, as they all come from alcohol, and disappear when this drug is taken away. A few writers have accepted this opinion, and declared that there could be no disease without alcohol, and even this drug did not produce uniform effects, hence the term disease was not accurate. Within a recent period a leading medical society discussed this question, and concluded that inebriety was a vice, and remediable only by moral means.

One man asserted that the only cure was to remove alcohol, others doubted any cure by medical means, and believed all alcoholics had a depraved brain, which could be reached only by conversion and the stimulation of the will of the patient. Such views coming from medical men at this time show the persistence of the delusive theory of moral causes, which was then urged so prominently by clergymen a quarter of a century ago. These and similar theories have become formulated into many of the great efforts to suppress this evil. Prohibition assumes that stopping the sale of spirits and removing alcohol is an effectual cure for this disorder. The efforts of the law by fine and imprisonment are based on the theory that the causes are the wilfulness of the victim and his reckless disregard of the interests of others.

Moral suasion by the pledge, prayer, and solicitation is based on the theory that the disease is only sin, for which conversion and change of heart are the true remedies. Thus nearly all the measures used to check inebriety are based on the theories that the causes are vicious immoral impulses which not only seek alcohol as an outlet but which alcohol develops in its worst forms. Hence the real remedy is punishment and fear, driving back the vicious nature and encouraging the better part of the man.

One of the great modern efforts to break up inebriety is by teaching to children in public schools the nature and effects of alcohol and the dangers from its use. This is a very important and significant advance toward the scientific study of the subject, and worthy of all encouragement. It is founded on the theory that ignorance and false teachings concerning inebriety are an active cause, the removal of which will largely do away with the evil. Unfortunately, the medical profession have not led in the education of the public concerning inebriety, but have followed, endorsing plans and measures for relief in a confused way. The Association for the Study of Inebriety, which has been over thirty years before the public urging the disease theory of inebriety, and its curability, is still largely unknown. Delusional theories of alcohol, based on mercenary and other interests, have been accepted as true by the public, and the medical profession, as a whole, are reluctant to change and admit errors of old-time theories and beliefs.

Alcohol in these later days has been studied with some degree of exactness, and the dense delusions which have prevailed concerning its action on the body are rapidly disappearing. A careful study of a large number of inebriates has brought out some facts which give an entirely different conception of inebriety and alcoholism, and the diseases which they represent. The term inebriety is used to describe the state of persons who are stupid or demented from alcohol, or other narcotic drugs.

Alcoholism, more accurately, refers to conditions which are specifically due to alcohol as an active or predisposing cause. It is not correct to call all persons alcoholics who use this drug to excess at times or continuously. Many cases when examined indicate that the use of alcohol is only accidental and by no means the cause. The following are examples:

A man jumped off a railroad train, suffering a severe shock by a fall on his head, and almost immediately he began to drink spirits to stupor. Another man, after a protracted illness from typhoid fever, drank constantly to great excess. Another person, after an exhausting period of overwork and mental excitement, began at once to drink spirits to excess. Innumerable instances of this class, dating from some profound change in the brain and organism, are marked by alcoholic excesses, and the use of alcohol is literally a symptom of some central lesion and not the disease itself. These persons were abstainers, or used alcohol in such moderotion as not to attract any attention.

and the sudden appearance of the alcoholic craze was a symptom of distress and pain demanding relief. Such persons are inebriates and not alcoholics. The true alcoholics, or subjects of alcoholism, are those who have been wine, spirit, and beer drinkers from early life, using it at the table with food, or as medicine for all pains and disorders.

The result of this use of spirits is alcoholism, either in paroxysms, with free intervals, or its continuous use without object or purpose. Thus persons in prosperous circles of life, who have used wine or beer with their food regularly from early life, and later take spirits as a medicine, or for any conditions real or imaginary, steadily increase the amount used, until intoxication [or continuous stupor follows, are alcoholics.

In the lower walks of life, where beer is used on the theory that it is a concentrated food, and where spirit-drinking is encouraged by the contagion of surroundings, faults of nutrition, and delusive theories of its value to both body and brain, alcoholism is the natural and inevitable termination. Many persons of both these classes are not stupidly intoxicated, or prominently disabled to perform their daily duties, but they are all more or less demented, with mental and physical incapacity to act normally.

Often in the alcoholic classes there are seen grave mental and physical defects, which have been intensified by the continuous use of alcohol from early life. In the families of the poor and degenerate, where the faults of environment and nutrition are prominent, the use of alcohol not only covers up these conditions, but makes the deviation from health greater, perverting growth and diminishing vitality. If to this is added defective heredity, the damage is intensified; and although the children may survive, and even reach middle life, they are defectives and degenerates, and of this alcohol is a very potent cause. The alcoholics of this country belonging to this class are largely foreigners, either the very rich or the very poor.

The rich are often imitators of customs in high life abroad, and adopt the use of wines at table to show their superior capacity for enjoyment, and continue to do so, unless they become disabled through sickness, poverty, or disease. If they are under strenuous mental and physical conditions, spirits are used to excess, and death from intercurrent disease is common. While the parents may continue to drink wines and spirits, without showing excess, the children born during this period, and brought up under these conditions, are practically alcoholics, having inherited a neurotic and alcoholic diathesis to use spirits for all forms of exhaustion. This diathesis and tendency are cultivated and increased through early life, and down into manhood, and end, in the vast majority of cases, in alcoholism and death. As an exception to the rule, certain children brought up to use spirits at meals in this country may continue moderate drinkers, and live an ordinary lifetime, but the vast majority become alcoholically diseased, and die in early or middle life.

Lower down in the circle the poor foreigner who comes here wedded to the use of beer daily, finds that its effects are more serious in this climate, and after a few years he is broken down, and dies from acute disease. His children may become abstainers, but usually develop into some form of degeneration which gives them a short life. The alcoholics from this circle of life furnish the large stock of criminals of the lowest type of tramps and paupers. From this stock the degenerates and defectives and the dangerous classes are largely recruited.

Fortunately persons of this class coming from the prosperous, and the very poor, who are literally alcoholics in the technical sense, are growing fewer and are early eliminated in the laws of survivals. The other or inebriate class comprises those who are physically and mentally crippled or poisoned and suffer from retarded developments, hereditary tendencies, and all degrees of paranoia. They are all that vast army of men and women, who, through neglect, overwork, and underwork, have precipitated and cultivated soils and conditions for the growth of spirit and drug diseases. They have what may be called a neurotic constitution, or neuropsychosis, with feeble powers of control, nerve instability and defective nutrition. Another term describing their condition is psychoneurasthenia; they are persons in whom brain and nerve failures are more prominent than any other defects.

Such persons have obsessions, impulsions, manias, phobias, states of morbid anxiety, with hesitating, uncertain control and conceptions of life. Forbes Winslow describes these persons as having hysterical brains and constitutions. Associated with this are varied nutritive disturbances and emotional exacerbations, heart irregularities, and acute and transient neuralgias. Another term is the deterioration type, or a class who are slowly or rapidly degenerating and growing feebler, persons in whom the power of resisting pain and discomfort is very feeble, and who are unable to adapt themselves to the changing conditions of environments. Remedies that are narcotic in their effects are most grateful, because they cover up the real conditions with a semblance of vigor and strength that is delusive to the mind.

The craze for alcohol, or any quieting narcotic, may appear at any time and they become inebriates. These persons cannot be called alcoholics, because the removal of this drug is not followed by restoration. On the contrary it often uncovers and brings to the surface other and more serious acute and chronic diseases. This is manifest in the large death rates from acute pneumonia or tuberculosis, noted in abstainers who have been drinkers. Serious functional heart disorders and local inflammation break out with or without cause at this time, and the general impression that the removal of alcohol has had some influence in the cause prevails. In reality, alcohol has only intensified the original degeneration and concealed the acute symptoms, and its use has been a symptom and not an active cause. There is undoubtedly a marked type of neurosis which develops into excessive spirit and drug taking, both with and without temptation. It may take on different forms, and does not always appear as a drug mania.

One symptom may be gormandizing, lack of self-control, and erratic credulity, combined with feeble judgment, low vitality, and physical-pain cowardice. In another, emotional extremes of great depression and exaltation from the most trifling causes. From moderate-drinking parents one son developed a maniacal dread of poverty, and spent his time amassing property and investing it in all sorts of ways to prevent loss. He starved his body, and finally drank alcohol the last two months of his life. The second son was a drug-taker from early life, using spirits and drugs alternately to avoid suffering and discomfort. Both were inebriates, and both had a constitution that was defective in balance and control. These defects were transmitted from their parents. A very large number of persons who suddenly begin the use of spirits in early and middle life suffer from

neurasthenic condition, with low vitality, and tendency to physical and mental exhaustion from the slightest strain. Often this debility is painful, provoking an intense desire for relief from every possible source.

This points to an inebriate constitution, which is very likely to develop into a mania for spirits and narcotics at any time. The removal of alcohol in these people is only a small part of the treatment and practically merely change the symptoms. The restoration must depend on the use of a great variety of restorative measures in exact surroundings. Many times this diathesis or peculiar defective organization is the result of conditions of life, hence the danger of treating exhausted and worn-out persons by giving alcohol or narcotics.

The use of these drugs focalizes and intensifies states of degeneration and organic changes from which recovery is impossible. The alcoholic is partially curable, and when the demand for alcohol and drugs is dispelled a prominent cause is removed. In the inebriate the suppression of this symptom is only turning the degeneracy into other directions and removing the narcotics which have covered it up. The intense egotism of reformed patients as to the finality of their cure is an indication of the delusive state of the brain. When this egotism is based on the effects of specific drugs or forms of treatment it is still stronger evidence of delusion. When the inebriate turns from one drug to another, or from one addiction or phobia to another, there is a progressive deterioration that cannot be mistaken. The alcoholic can be relieved temporarily by long abstinence, exact living in the best surroundings, but his restoration or cure in the sense of totally removing the causes is impossible. Abstinence from alcohol may be complete the rest of his life, owing to physiological change, but the defects of cell and brain circulation and metabolism of the body can never be fully restored. He is crippled and permanently incapacitated, although he may do much work along certain levels of sane normal life.

The inebriate, on the contrary, is often permanently restored, the defects of constitution, if acquired, may be remedied in a measure, and the particular conditions of exhaustion and feebleness which preceded the drink craze can be overcome. It is a question of determining to what extent the brain and body have sustained damage and injury, and of removing these states. The desire for spirits is easily overcome by increasing the vigor and correcting the disorders of the system.

This is not a matter of drugs alone, but is a question of the long use of means for nerve and brain rest. The very best statistics from the most reliable authorities show that over one-third of all inebriates who go under treatment and remain from four to ten months are permanently restored, and remain abstinent, living temperate lives for periods of fifteen or more years. This is the most hopeful indication, and shows how much can be accomplished by exact scientific study and the application of proper means and measures for relief and restoration of the body and brain.

Pneumonia.—Indications for treatment are relief of toxæmia, maintenance of circulation, and meeting complications. Toxæmia is best relieved by purging and sweating. The circulation is improved by vigorous cupping of the chest, by bleeding when the right heart becomes distended, by hypodermoclysis of salt solution, and strychnine hypodermatically in large doses. The mouth should be kept clean.—Delancey Rochester, *New York State Journal of Medicine.*

MINUS CYLINDERS.

By F. W. HIGGINS, M.D.
CORTLAND, N. Y.

My paper is modelled after a Scotch Covenanter's sermon. My text is: "And if the righteous scarcely be saved, where shall the ungodly and the sinner appear?" My firstly is the proposition that fitting a pair of glasses is a problem that requires all the skill which medical training can bring to it. My secondly shall be the conclusion that this problem is totally beyond the so-called graduate optician. As thirdly may appear the exhortation that we, as physicians, should give more attention to the symptoms of eye-strain.

The symptoms of eye-strain are multiple, and their origin in the eyes is often overlooked. About the eyes themselves it will be seen that the lids are red, the edges are crusted, or styes appear; the lids feel rough, as if there were sand or sticks in them; it is difficult to hold them open after reading a short time. The eyeballs ache. There is supraorbital pain or a pressure back of the eyes; letters on the page run together if one persists in using the eyes, and black spots dance about in the field of vision. All these local symptoms are easily referable to the eyes. But other symptoms at a distance may be added or be present when the patient gives none of these plainer evidences of eye-strain.

Pain in the occipital region is due to eye-strain in almost all cases. The feeling termed a pressure at the base of the brain, described in connection with neurasthenia is to be treated by glasses, not medicines. When patients call themselves nervous, and cannot put their bad feelings into words, the eyes are often the cause. Nervous dyspepsia and gastralgia demand an examination of the eyes before any other treatment. Chorea in young persons, and the various jerkings of the face and contortions of the body we call choreiform, can often be stopped by fitting proper glasses. While true epilepsy may not be cured by glasses, I have recently seen a marked case of relief in epileptiform convulsions. These symptoms of eye-strain, some of them manifest in the most distant parts of the body, must be met by every practitioner. They may be due to astigmatism, or want of muscular balance. They are often induced or made worse by badly fitting glasses. The mistake most often made is in putting on minus cylinders. In looking over my last five hundred refraction cases I have noticed eight whose symptoms had been greatly aggravated by trying to wear minus cylinders given by opticians.

Allow me to give some details: One case was that of a student twenty-four years old. She had nervous symptoms enough to occupy my whole paper. She came to me with the diagnosis of floating kidney, which I could not detect. Her abdomen was tense, her hands numb; she had hot feelings; her head felt heavy and dull. I found she was wearing minus cylinders—75 ax. 90. for each eye. She had esophoria of 15°. Here was evidently cause enough for her multifarious symptoms. Examination showed that she had a marked degree of mixed astigmatism accepting—75D. = +1.75 D. ax. 85. With this correction and gymnastic exercise for the internal recti muscles she was enabled to go on with her school work, her condition greatly improving from week to week.

Another patient with mixed astigmatism, who was wearing improperly fitted minus cylinders was a bank cashier, aged thirty-six years. For many years he had worn—4.00 D. cylinders with the rule. He had frequent attacks of migraine, and a constant bad feeling in the back of his head. The blood-ves-

sels in his temples stood out like whip-cords. By wearing the correct lenses he has been able to perform his exacting work with great relief.

A similar case was that of a typesetter, aged thirty-two. He could see at a distance with his minus cylinders, but everything blurred at close work. He also proved to have mixed astigmatism. His lenses were decentered in to assist his very weak interni muscles. He reported six months later that he could do his work comfortably.

One typical case was that of a farmer, aged thirty-five. He came to me wearing weak minus cylinders, fitted by an optician fifteen months before. They had made him see distinctly, but his eyes were bloodshot. His glasses were changed to weak plus cylinders against the rule, which entirely relieved him. I will pass over other similar cases to mention one only. This was a traveling salesman, aged forty-two. He had a heavy feeling over his eyes; his lids were red. He could not read long; he was nervous, and had frequent headaches, for which he was obliged to take acetanilid. At times his eyes would blur; he would become dizzy, and stagger in walking. One would suspect some cerebral affection. But he was wearing minus cylinders, and had esophoria. The weakest plus glass blurred his vision, but by argument, and explaining the reason for it, he finally began wearing the same strength cylinders, made plus instead of minus. Eight months later the symptoms were greatly mitigated; overwork was still possible, but he was comparatively happy.

It was easy to see how the mistake was made of requiring these people to wear minus cylinders. Astigmatism was present in all cases. Astigmatism is a greater curvature in one meridian of the cornea than in the meridian at right angles to it. The endeavor to produce a distinct retinal image with such a distorted corneal lens calls for excessive and unnatural action of the ciliary muscle which controls the accommodation of the crystalline lens. This often results in spasm and overaction of the ciliary muscle, and thus an increased curvature of the lens, and a transient or functional myopia. If now this apparent myopic astigmatism be corrected by minus cylinders, the overaction of this muscle must be kept up constantly in order to see plainly at all. Thus the eye-strain is aggravated rather than relieved by the glasses. In these cases the use of a mydriatic may be absolutely necessary in order to refract the eye properly. But opticians cannot use atropine in the eyes, even if they suspected its necessity.

Another condition which complicated almost all these cases in which the patients were in misery from trying to wear minus cylinders was the presence of esophoria. Esophoria is a tendency of the eyes to turn in. This overconvergence is to be expected with hyperopia or hyperopic astigmatism, and often disappears when corrected by convex lenses. Convergence and accommodation are such associated actions normally that the nerve centers for each come to act conjointly. So when one is called upon for excessive action the other acts excessively. Classes which would lessen the action of the ciliary muscle would also correct the overaction of the internal recti. But if there is already esophoria, wearing minus cylinders would call for increased action of the ciliary, this would produce a consensual stimulation of the convergence, and so the esophoria would be made worse and a vicious circle established.

When we begin to understand how complex is the problem of fitting the proper lenses in such cases we do not wonder that opticians fail. The surprising thing is that intelligent patients, and even physicians expect that they can succeed. The usual history is that the sufferer has gone back to some optician time after time to have his glasses changed. Finally, the optician becomes tired, and the wearer of the lenses desperate, and the patient appears in a doctor's office willing to pay a fee for examination of his eyes.

Is it not strange that it should not be deemed necessary for one to have a medical training before undertaking the treatment of the most delicate organ in the human body? But I suppose doctors are found in every place who tell their patients to go either to an oculist or to an optician and get their eyes fitted. One clever young physician of my acquaintance gives up his office two days in the month to a peripatetic optician.

The case would be bad enough were all the opticians as honest as some of those whom I know. But from the cheap glass-peddler to the so-called professor who puts up at the best hotel in the city for a few weeks, many of the opticians are out simply for the money there is in the business. Much harm results. Let me illustrate by one case of several I have seen. A stenographer had severe headaches after obtaining a fine position. Six months before I saw her she had consulted a "professor" who came to our city monthly for a few days. He had furnished her a pair of glasses at a price which precluded her getting another pair for some time. Her headaches grew worse. She was on the verge of giving up her position when I chanced to examine her eyes. I found she had one diopter of astigmatism with the rule, in each eye. Her glasses, which she was faithfully wearing, in the fond hope that they would cure her headaches were plain window glass. With the proper cylinders she did her work easily.

At times physicians also fail to give entire relief to symptoms of eye-strain, as I know to my sorrow. My contention is that if they succeed only moderately well, while recognizing the factors which complicate the problem, where shall the ungodly and the sinner appear who do not know, and sometimes do not care, for the conditions of success?

I have reserved to the last one case in order to illustrate the evil effects of wearing minus cylinders, and also the close connection which should subsist between fitting glasses and the rest of the practice of medicine. Mrs. M. was brought to me by Dr. Forshee of McGraw, on July 15 of last year. She had all the symptoms which each one of us have heard detailed by little nervous women. She could not sleep; she felt in a constant strain; her face was flushed. Three times recently she had fallen to the floor in an epileptiform condition, having also had lighter attacks. Together we searched for causes of her nervous breakdown. She had borne one child, and the uterus was tender and large. I suggested her eyes, but she had worn her present glasses eight years, and thought that they were all right. So she was treated for the uterus and by general measures for a short time, with but little relief. Her physician then insisted that she come back for a study of the eyes. It was found she had been wearing strong minus cylinders all these years, when her true correction was R + 1.00. D. cyl. ax. 90. L. + .25 = + .75 D. ax. 80. She is still under observation, but very greatly improved. Imagine how impossible it would have been to have restored her to household duties if she had continued wearing minus 1.25 D. cylinders! I am sure that I would have an attack of vertigo in one day by wearing that amount of improper lenses.

I conclude that to prescribe glasses properly requires a medical training, and that as physicians we all should recognize the symptoms of eye-strain.

GASTROSTOMY FOR STOPPAGE AT THE CARDIA.

By H. W. LINCOLN, M.D.,
BROOKLYN, N. Y.

A PATIENT, Miss P., was referred to me by Dr. W. A. Little on March 10, 1904, with the following history: Age, forty-nine years; mother died of rheumatism; father of tuberculosis; one grandparent passed away of malignant disease of the stomach. This lady has complained since July, 1903, of progressive inability to get food into the stomach; vomiting of mucus, distention, constipation, dragging pains from the back. One to two years previously she had mucous discharges from the bowels. There is not and never has been any pain, either localized or general. There has been no blood vomited or passed by bowel. Loss of weight amounts to about fifteen pounds. The picture of emaciation would appear extreme but the patient has never weighed more than 110 pounds. Physical examination revealed a low position of the stomach and a freely movable right kidney, as might be imagined from the general appearance. The material brought up (not vomited) resembled that coming from an œsophageal pouch. The woman previous to coming under the care of Dr. Little had been treated at one of the large institutions in Manhattan, and a diagnosis of chronic gastric catarrh formed, after, as was reported, several test-meal examinations had been made. I tried three times to introduce the tube, but each time it met resistance seventeen inches from the incisor teeth. At the suggestion of the doctor we placed the patient in the Bushwick Central Hospital, and she was turned over to the service of Dr. Campbell. On March 16 Dr. Campbell made two *x*-ray exposures, at which I was present, and each time the bougie stopped about 16½ inches from the incisor teeth. The patient came to operation at 12.45 P.M. On March 18 she weighed eighty-five pounds and was, to say the least, on the verge of starvation. A gastrostomy was chosen, as a radical operation was deemed inadvisable on account of the extreme weakness of the subject.

The actual operation consumed about twenty minutes, and the patient was completely out of the ether at 3.30 P.M. Four ounces of warmed peptonized milk and one-half ounce of whiskey were introduced into the stomach immediately after operation, and nourishment has been kept up by that organ ever since. Rectal feeding was continued until March 25, when the canal became a bit irritable. At first feeding was done every four hours; at the present time and for the past two weeks nourishment has been given every three hours. A feeding consists of an ounce of whiskey, four ounces of milk, half a drachm of sodium bicarbonate, half an ounce of olive oil, the white of one egg, one ounce of water, and five minums of tincture of strophanthus. Strychnine sulphate, gr. $\frac{1}{30}$, was used the first three weeks, but latterly seemed to be somewhat disagreeable to the patient. She has also been taking iron since April 12. There has been no untoward symptom since the operation, save on April 5 and 10, when the stomach showed slight signs of irritability and there was a very minute quantity of bloody mucus regurgitated. Stoppage of the strychnine seemed to allay this.

There were two salient points of interest in this case: (1) the length of time elapsed with no pain nor tenderness—in fact, no complaint whatsoever except that the patient was gradually starving; (2) that a diagnosis of chronic gastric catarrh could have been made, and how test-meal examinations could have been reported. I might add that the bowels, formerly constipated, have been acting voluntarily practically since operation. The temperature never reached 101°.

From the date of presentation before the Brooklyn Medical Society, on April 15, 1904, until about May 1, everything went along smoothly, the patient getting into the fresh air, which seemed to act with wonderful tonic effect. At this time a change for the worse set in and progressed most rapidly until, on May 6, death put an end to the general malignant intoxication. I was fortunate enough to secure an autopsy, with the following result: The field at and near the cardia was infected to such an extent that it was impossible to remove the stomach and malignant growth intact. The œsophagus was involved for a distance of about two inches upward toward the pharynx. The lesser curvature was entirely covered anteriorly and posteriorly, while at the cardiac orifice there was a growth of characteristic hardness as large as a walnut. The pancreas was practically one carcinomatous mass. The liver was not involved; the lumbar lymphatics were studded with malignant nodules. The stomach was greatly atrophied, holding not over twelve ounces. The operative wound was clean and perfectly healed.

I venture to publish this history in view of the fact that from the beginning, nearly ten months ago, there had been no pain nor tenderness at any time.

113 HANCOCK STREET.

THE STOMACH REFLEX AND PERCUSSION OF THE STOMACH.

By ALBERT ABRAMS, A.M., M.D.,
SAN FRANCISCO.

THERE are numerous methods suggested for determining the size, shape, and position of the stomach, but unfortunately the methods that are simple are inexact and those that are relatively exact are complicated. As a rule, an accurate outline of the greater curvature of the stomach suffices in the majority of instances. We cannot attain our object by ordinary percussion, owing to the very pertinent fact that gastric tympany is not distinguishable from the percussion note of the surrounding intestine, notably the colon. The elicitation of the stomach reflex,* however, will obviate the foregoing difficulty. To evoke this reflex, we must first locate the half-moon-shaped space of Traube, which is bounded above and latterly by the contiguous borders of the liver, lung, and spleen. This space yields normally on percussion a tympanitic sound, owing to the presence of the cardiac end of the stomach. Even though the tympany in this area is absent, one may nevertheless proceed to evoke the stomach reflex. Next we firmly fix our pleximeter in this region and strike the latter a series of vigorous percussion blows with a percussion hammer and then proceed to percuss the exposed anterior surface of the stomach, which will now be found to yield a dull or tympanitically dull sound, and the dull area can, without difficulty, be distinguished from the contiguous atmosphere of tympany. The dulness of the gastric area subsequent to concussion after the technique described constitutes what the writer has called the "stomach reflex." The duration of the reflex in question varies from one-half to one and one-half minutes; it is therefore imperative to proceed with percussion for the purpose of defining the

* "The Intestinal and Stomach Reflexes," *Medicine*, January, 1904.

gastric area immediately after concussion is made in the Traube area. If, for any reason, the reflex is abolished before topographic percussion is completed, the reflex can again be elicited and the complete area of the stomach outlined. Percussion of the epigastrium by means of the hammer or fingers will abolish the reflex at once. If, for any reason, a pleximeter and hammer are not at our command, concussion of the Traube area may be executed with the flat surface of the fingers of the closed hand, although this manœuvre will be found less effective and agreeable.

The stomach reflex has been variously investigated by the writer with the gastrodiaphane and the Röntgen rays. Investigated according to the latter method, after the stomach is moderately distended by air, the stomach fundus is observed to recede fully an inch or more. The stomach reflex may be variously employed in diagnosis, as may be determined by reference to the writer's original contribution. Suffice it to say, at this time, that not only do we possess in the stomach reflex a simple means of defining the stomach but likewise of gauging the motor power of that organ. The latter may be gauged by the intensity of dulness incident to the concussion blow, which, however, should be uniform. It remains for the writer to explain the altered percussion sound in the stomach reflex.

We will concede that the stomach normally yields on percussion a tympanitic sound, the pitch of which necessarily varies. Thus, if the air or gas in the stomach is under considerable tension, pitch becomes higher, and the volume and intensity so decrease that percussion will yield a dull sound or dull tympanicity. Now in the stomach the tympanitic sound is caused by the periodic vibration of the air or gas within it. If, for any reason, the gastric walls are made tense, vibration is induced by percussion not only of the contained air or gas but also of the walls; the result will be that the vibration of the walls and gas become mutually disturbed and the conventional tympanitic tone is lost. This is the Skodaic interpretation of the condition which exists when dulness supplants tympanicity. We are constrained to assume that in the stomach reflex the walls have become tense, thus putting the air or gas in the stomach under increased tension, and for this reason we have the physical elements necessary for the transition of a tympanitic to a dull sound. We have reason to assume that in the stomach reflex the gastric walls are brought into a condition of contraction.

A New Method of Suicide.—A nurse at one of the Paris hospitals not long since tried a new way of committing suicide—namely, by swallowing two tubes of Eberth's pure culture of the typhoid bacillus. On the following day and the day after that she felt no inconvenience. On the third day she had some headache but no fever. On the sixth day she felt heavy and stupid and experienced great weakness in her legs, being obliged to take to her bed. On the seventh day her temperature was, in the morning, 37.6° C. and in the evening 38.6° C. On the eighth day she had two attacks of epistaxis and her temperature in the evening was 40.2° C. Several rose spots were also visible. On the tenth day serum reaction was positive. Otherwise the typhoid fever followed its normal course, but it was a very severe attack and the patient had in all 176 baths. The remarkable points of this case are the very short duration of the period of incubation—namely, only two days—and the rapid appearance of the rose spots, eight days after infection. M. Duflocq and Voisin, who reported the case, explained the very short duration of the incubation period by the large quantity of bacilli which were introduced at one time into the digestive tract.

Hypertrophied Rectal Valves and Their Treatment.—Wells Teachnor states that the one essential anatomic feature that distinguishes the rectum of man from other animals is that the mucous membrane is reduplicated into folds containing muscular fibers, blood-vessels, and nerves, constituting veritable valves, which partition the cavity of the gut into as many chambers as there are valves. They occur alike in the old and young and in the male and female. The average number is three. If the function of a normal rectal valve is beneficently to retard the descent of the fæces, it must be true that it may be the especial property of the valve in certain other normal conditions maliciously to obstruct the descent of the fæces. As to operation, the writer speaks of the clips devised by Pennington and somewhat modified by Gant. These clips cut out an elliptical piece from the free border of the valve, usually without pain and danger of hemorrhage, and should the peritoneum be opened —and there are no means of knowing when it is not involved in the valve—adhesions from plastic exudations are formed before infection takes place. The writer in conclusion says that the rectal valve is a permanent constituent of the rectum. These valves become hypertrophied and obstructive from an inflammatory condition produced either locally or by a constitutional dyscrasia. The benefit derived from operative procedure depends upon the proper selection of cases. Valve section will not relieve constipation. Operation is beneficial in selected cases.—*The Cincinnati Lancet-Clinic.*

The Diagnosis of Pernicious Anæmia.—T. Law Webb declares that it is necessary in any severe anæmia to ascertain by examination of the blood what changes it has undergone, so that we may definitely know which type of anæmia we have to deal with. This examination must include a count of the red cells, an estimation of the percentage of hæmoglobin, and a careful search over several stained films for megaloblasts. Most observers believe that Ehrlich is correct in saying that in pernicious anæmia the blood is megaloblastic and has a high color index. Exceptions to this rule are exceedingly rare. The writer describes a simple procedure for use at the bedside. After pricking the skin, he allows a 10 c.mm. pipette to fill itself with blood, then takes it out of its handle and drops it bodily into the tube of Pacini's fluid. This must be corked at once and shaken gently to and fro until the blood is diffused throughout the fluid. Next the Von Fleischl pipette is filled with blood, dipped into the wider tube containing the water, and moved quickly from side to side so as to mix its contents with the surrounding liquid. The tube must then be corked securely. Finally a few dried films are to be made, and the practitioner is then in possession of all that is necessary for a complete examination of the blood in a case of pernicious anæmia. The writer insists upon the use of the mechanical stage, combined with slight over-staining before any confident statement is made as to the presence or absence of megaloblasts. As to the exceptions suggested above, in certain anæmias due to worm-infections (with parasites such as bothriocephalus and ankylostomum, for instance), Ehrlich believes that the blood may exactly resemble that of pernicious anæmia. Good observers have recently found, however, that these anæmias are usually of the chlorotic type, having a low color index, and not showing megaloblasts. Moreover, in the few recorded cases in which the blood was truly megaloblastic, the color index was only moderately raised. In a few cancer cases the blood may conform to the type found in pernicious anæmia. But in the greater number of cases of malignant disease, the blood changes are of a type exactly opposite to those of pernicious anæmia. The writer has seen a case of Raynaud's disease in which the color index was high, but yet there were no megaloblasts or megalocytes, nor was there any poikilocytosis. Taking the whole examination together, there could be no mistake in diagnosis.—*The Birmingham Medical Review.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51, FIFTH AVENUE.

New York, Sept. 3, 1904.

HEALTH CONDITIONS OF PANAMA.

THERE is still considerable difference of opinion as to whether Panama and neighborhood can be rendered sufficiently healthy for white men to live therein without serious risk. Some say that this can be brought about, while others assert that no precautionary measures will make of the Isthmus region a locality in which men of the white race can exist in even comparative safety, and that health stations must be selected in available situations to serve as safety valves. Of course it is notorious that the climate and sanitary conditions of the Panama district are at present peculiarly deadly to northern people, and it is doubtful if any improvements will materially change this state of affairs. At the same time it would seem reasonable to suppose that drainage and other obvious and energetic steps taken in this direction should have a beneficial effect upon the situation. Careful living, especially abstinence from alcohol, is a prime factor to be considered by the individual in the solution of the health problem in the projected canal zone.

Public Health Reports of August 5 contains the report of Assistant Surgeon Pierce from Panama for the period extending from January to July, 1904. During the six months of 1904 there occurred 541 deaths in a population of 20,000. American population 100, deaths, 4; rate per 1,000 per year, 80. Panaman population, 14,200, deaths, 360; rate per 1,000 per year, 50.70. West Indian population, 2,500, deaths, 50, rate per 1,000 per year, 40. Chinese population 1,200, deaths, 17; rate per 1,000 per year, 28.32. All others population, 2,000, deaths, 110; rate per 1,000 per year, 110.

A fact worthy of notice is that more deaths occur between the ages of thirty and forty than at any other ten-year period of life except that below ten years of age, which latter period includes the still births. Dr. Pierce thinks that the only explanation of this fact is that during this time, which should be the prime of life, acute diseases tend to terminate fatally, because of weak heart action and sluggish liver, due to the use of alcohol and tobacco in early life and long residence in a tropical climate.

It goes without saying that a death rate based upon so small a population of Americans as in Panama, most of whom have been living under similar sanitary conditions with the natives, has practically no bearing upon what the death rate would be for Americans on the Isthmus. The West Indian population is composed almost entirely of Jamaican negroes and includes many women and children.

The Chinese population is composed practically of adult males only, which accounts for the relatively low death rate among these Orientals, who live under worse sanitary conditions and more closely crowded than any other class in Panama.

Of the diseases reported nearly all the cases of "colic," to which affection many deaths were attributed, occurred in young children. This term includes nearly every gastrointestinal trouble of children. "Many of the cases reported as dropsy," says Dr. Pierce, "might be combined with those reported as liver disease, as there is a general tendency to hepatic troubles, due to use of alcohol, eating a great deal of meat, and the tropical climate. Those cases reported as dropsy in children and young adults were probably uncinariasis. No examination of fæces being made by the doctors here, hookworm disease is never reported, although it has been recognized on the Isthmus by the American doctors."

All fevers are practically of malarial origin, while typhoid is absent or rare. Many cases reported as pneumonia are believed to have been acute tuberculosis, due to the fact that the Spanish term used in a large number of cases could be translated as almost any disease of the lungs. Filarial diseases are present, but no deaths have ever been reported due to this cause. Probably here again the diagnosis has been incorrect, and some of the deaths attributed to albuminuria and abscess and maybe some of the fevers were owing to filarial affection. There were six deaths from yellow fever, four of which occurred in natives and two in Europeans.

The lesson to be learned from a consideration of the above facts would seem to be that competent well trained medical men are badly needed in the canal district. So long as inaccurate diagnoses are made it is impossible to publish with any degree of correctness proper records of the causes of death.

Another point which stands out prominently is that if a white man is to keep in good health on the Isthmus, he must be careful in his diet, especially in respect to alcohol, and live generally under those sanitary conditions which have been demonstrated as most applicable to tropical climates. Much can doubtless be done by thorough sanitation to improve the canal route from a health standpoint, but residents can do more to retain their health by pursuing a rational mode of life.

TREATMENT OF INTESTINAL AUTO-INTOXICATION.

PROFESSOR COMBE of Lausanne treats of this subject in the *Archives de Médecine des Enfants*. Referring to treatment, the writer thinks that the only rational mode of procedure is by diet. Nitrogenous food should be diminished, and the intestine filled with carbohydrates. Farinaceous food is mainly indicated, supplemented by milk. Milk has a strikingly antiputrescent effect in the bowel, an action which is also very markedly possessed by fresh cheese. Dr. Combe pins his faith to farinaceous foods. They are slowly absorbed, giving off lactic and succinic acids gradually. They should be given in large amounts, but in small and frequently repeated meals the following general rules for the diet are recommended: (1) Not to drink with meals; and not to eat when drinking. (2) To divide the nour-

ishment into numerous small meals, taking alternately a solid and liquid meal. (3) To rest lying down, either on the back or on the right side for an hour after each meal, but not to go to sleep. (4) To exclude from the diet all foods which are capable of acting as culture media for the proteolytic bacteria. (5) To avoid all meat that is "high" or apt to undergo fermentation. (6) If enteritis be present, to avoid all food which contains a large amount of cellulose. (7) In severe cases of autointoxication or enteritis, to give up meat entirely, and even milk at first. (8) To prefer, when possible, raw milk to boiled, and either to sterilized milk. (9) To take into the alimentary canal as much farinaceous food as possible.

It must be borne in mind that this diet is but a temporary and medicinal one, and that as soon as its effect has been produced, a fresh element should be added to it, such as pasteurized milk and blackberry juice, so as to avoid scurvy. The next object is to get rid of the products of putrefaction in the large intestine. With this end in view, the putrescible matters should be washed out of the top of the bowel by a thorough irrigation of the colon. Such irrigation serves the further office by means of partial absorption, of not only allaying the patient's thirst, but of producing a beneficial diuresis, and of washing out, as it were, the liver, the blood, and the kidneys. As a rule, nothing answers so well for the irrigations as sterile salt solution, but in some cases solutions of tannin, columba, or ichthyol and oxygenated water may be used. Boric acid is not to be recommended, as it may become absorbed, and to give rise to symptoms of poisoning. The aim now is to lessen the putrefaction of nitrogenous matters in the large intestine. An ordinary purgative, as castor oil, or a saline given alone, does not accomplish this result, merely stirring up the débris in the bowel and tending to aggravate the symptoms of autointoxication, and is found to be followed by an increase of the sulphoethers in the urine. A disinfectant dose of calomel, however ($\frac{1}{3}$, $\frac{3}{4}$, or $1\frac{1}{2}$ gms., according to the age of the patient), given twice at intervals of two hours, and followed by castor oil, has a distinctly beneficial effect. This should be repeated after ten days, and afterward, at longer intervals. The last measure to be taken is to favor the elimination of those poisons which have already found their way into the circulation. Irrigation of the bowel generally effects this purpose, but in severe cases, large subcutaneous injections of sterilized saline solution, may be used.

Prevention of Typhoid Fever.

Dr. William G. Daggett read a paper on this subject at the annual meeting of the Connecticut Medical Society, held on May 26, 1904. Dr. Daggett takes the view presented by Dr. John S. Fulton in the *Journal of the American Medical Association*, January 9, 1904, that typhoid fever is essentially a rural disease and that its propagation "is in general from the country to the town rather than from town to country." The writer thinks that in our present methods of fighting typhoid fever, there is not sufficient attention paid to prevention. In order to strike at the root of the matter, infection should not be awaited, but its occurrence should be anticipated. Dr. Daggett thinks that this can be done only by comprehensive rural sanitation. By such means an effective warfare can be waged against the pollution of water and milk, the two most prominent factors in the dissemination of typhoid fever, as well as that of garden produce.

The meal privy is pointed at as the original plague spot. This building is generally located wherever most convenient, and its situation is seldom or ever based upon sanitary considerations. It is cleaned or screened but rarely, and its vault is never disinfected. As a matter of ordinary precaution against the spreading of typhoid fever, it should be located very carefully, thoroughly screened so as to keep away flies, and should be disinfected daily whether or not there is sickness on the premises.

The author deems that the first step in the direction of reforms should be the formulation of the best practicable methods of keeping privy vaults in a good sanitary condition. The next, the appointment of a number of State sanitary inspectors whose duty should be to make a complete sanitary survey of the State, with power to condemn improperly located or improperly managed privies. They should exercise a general supervision over the sanitary condition of farm buildings generally, and endeavor to instruct those connected with the farm in the best methods of keeping the same free from the germs of infection.

Opium Smoking in New York.

A young lady artist, walking on Seventh Avenue in this city the other day, was attracted by some cups she saw in the grimy window of one of the Chinese curio shops which have sprung up here so numerously in the past year or two. She entered and asked to see some cups, but the Chinaman inside was strangely indifferent to the wants of his customer and could hardly be induced to show her anything but one or two broken bits of porcelain. During the time she was talking with the proprietor she noticed a rather well-dressed man come in and say a word in a low tone to a Chinaman in the rear of the shop. Instantly a door opened and she could see down a long dark corridor in which many hats were hanging. Feeling rather uncomfortable in the place, the young lady left the shop and the Chinaman called after her, with a smile, "You come back tomollow?"

This girl had wandered innocently into an opium "joint," the number of which in this city is increasing alarmingly. Not all of these places have smoking rooms attached, their trade being chiefly in opium pills which are bought by dissolute women and others who "hit the pipe" in their own rooms. The character of these places is notorious, but the police, for some reason best known to their superiors, put no obstacles in the way of business. The Government Opium Committee, which has made a thorough study of the opium habit and the opium trade in the Orient, is said to have recommended the issuing of a license to all inveterate smokers in the Philippines. Were such licenses issued in New York for a moderate fee, the income of the municipality would be very appreciably increased. The suppression of these dens is an undertaking in which the Commissioner of Health might legitimately join forces with his colleague the Police Commissioner.

Some Medical Lessons of the War.

Dr. Suzuki, surgeon-in-chief on Admiral Togo's flagship, has contributed to the *British Medical Journal* some notes on the present war. He advises that clean linen be worn during an action, to obviate the danger of shells or bullets carrying into the wounds pieces of clothing which, unless clean, are likely to set up septic infection. Dr.

Suzuki states that most of the wounds observed by him caused by shell fire were lacerated and larger than bullet wounds, and he therefore recommends the use of larger first-aid packages. He suggests that two operating rooms be provided for in different parts of every ship, but recognizes the fact that serious operations whenever possible should be performed on the hospital ships. He is of the opinion that that side of the ship which is firing, is more suitable for the disposal of the wounded than is one that is not firing, because fragments of bursting shells are dispersed in a radiating manner. Dr. Suzuki thinks that the time will come when all combatants will wear protecting masks and jackets.

News of the Week.

Washington Threatened with Typhoid Fever.—Some apprehension has been caused by a warning from the District Board of Health that there is danger of an epidemic of typhoid fever in the city. The source of danger is at Mount Savage, near Cumberland, Md. The town has an epidemic of typhoid fever, there being 120 cases, and the drainage is into a creek that empties into the Potomac. The returns for August show there were more than fifty more cases in the district during that month than in July. In the winter of 1899–1900 a severe outbreak of typhoid fever in Washington followed closely on an outbreak at Cumberland. The health authorities are urging the boiling of all water used for drinking or culinary purposes.

Yellow Fever in Texas.—A despatch from Austin says that the Texas State Health Department has been informed of the breaking out of yellow fever at the government military post at Brownsville, Texas. One death was reported last Saturday, and several cases are said to exist there. This is a good opportunity for a trial of the "safe and sane" method of dealing with a yellow-fever outbreak—the Havana method, for example, as instituted by Colonel Gorgas when health officer of the city.

Typhoid Fever in the Bronx.—A small epidemic of typhoid fever exists among the Italian laborers working on the Jerome Park reservoir. It began about three weeks ago, when twenty-five cases were found in one of the laborers' settlements in the Bedford Park section, and now it is estimated that there are over 200 cases. Fordham Hospital is filled, and many patients have been sent to the Harlem Hospital and to Bellevue. A temporary pavilion is being built on the grounds of the Fordham Hospital. There is apparently no danger of contamination of the city water supply, as the reservoir on which the Italians are working is only in process of construction, and will not be in use for a long time.

Sanitary Provisions Nullified by the Courts.—A justice of the Supreme Court in Brooklyn has recently delivered an opinion, which, if supported, will tend to obstruct the Board of Health in its efforts to preserve the purity of atmosphere so necessary to the health of city dwellers. In setting free a man who had been arrested for allowing black smoke to issue from the chimney of his molding mill, the justice said that "that part of the Sanitary Code, which forbids any owner, lessee, tenant, occupant, superintendent, manager, fireman, or any other person, where business is done in the city of New York, to cause, suffer, or allow smoke to escape from any such building, and makes it a crime so to do, is unreasonable, in restraint of trade, against public policy, and void."

The Society of Chemical Industry, an international association of chemists and analysts, will meet in this city on September 7, under the presidency of Mr. William H. Nichols, who succeeds Sir William Ramsay. After the close of the meeting a special train over the Pennsylvania Railroad will take the visitors on a tour of the principal manufacturing cities between here and St. Louis. Four days will be spent at the world's fair to give them an opportunity of attending the international congresses. On the return trip, after visiting Chicago, Detroit, and Buffalo, the party will disband in Boston.

Pan-American Medical Congress.—President Amador of the Republic of Panama has appointed the following officers of the Fourth Pan-American Medical Congress, to be held in Panama the first week in January, 1905: *President*, Dr. Julio Ycaza; *Vice-President*, Dr. Manuel Coroalles; *Secretary*, Dr. Jose E. Calvo; *Treasurer*, Dr. Pedro de Obarrio; *Committee on Organization*, Drs. J. W. Ross, J. Tomaselli, and M. Gasteazoro. There will be but four sections, to which the following officers were appointed: *Surgical Section*, Major Louis LaGarde, President; Dr. E. B. Harrick, Secretary. *Medical Section*, Dr. Moritz Stern, President; Dr. Daniel R. Oduber, Secretary. *Section on Hygiene*, Colonel W. C. Gorgas, President; Dr. Henry E. Carter, Secretary. *Section on Specialties*, Dr. W. P. Spratling, President; Dr. Charles A. Cooke, Secretary.

Dr. Kenneth W. Millican of this city, for the past six years associate editor of the *New York Medical Journal*, has resigned in order to take entire charge, including the editorship, of the *St. Louis Medical Review*. Dr. Millican is well fitted by long experience for the duties which he has assumed, and we can confidently predict for him success in his new undertaking.

Dr. William H. Welch of Johns Hopkins University has just completed a course of lectures on Infection and Immunity at San Francisco, it being the ninth course of the Lane lectures at the Cooper Medical College. A large attendance attested the appreciation of the lectures by the members of the profession in the city.

Dr. W. P. Dunbar of Hamburg has come to this country to take charge of a section of the German exhibit at St. Louis relating to hay-fever. He has, as is well-known, devised a method of treatment of the disease by an antiserum, obtained by injecting the poisonous albumin of certain kinds of pollen into horses. Dr. Dunbar is a native of St. Paul, Minn., but lives in Hamburg, being the head of the State Hygienic Institute in that city.

Dr. E. H. Bruns, House Surgeon at the Cincinnati Hospital, was one of two candidates who successfully finished the army examinations held at Fort Thomas, Newport, Ky., last week. Five of the seven candidates failed.

Library for Cooper Medical College.—Under a bequest made by Mrs. Pauline C. Lane, who was the wife of the late Dr. L. C. Lane, the Cooper Medical College of San Francisco is to receive a medical library which, it is claimed, will surpass any similar collection in the West. Work on the building has already begun.

The Oldest Living Graduate of the Missouri Medical College.—*A propos* of the statement recently made in an obituary notice, that Dr. William D. Spore of St. Louis was reputed to be the oldest living graduate of the Missouri Medical College, Dr. J. D. Collins of Covington, Ky., writes that he took his degree from the Missouri Medical College, then the medical department of Kemper College, in 1845. As Dr.

Spore was then only four years old, it is evident that Dr. Collins' graduation must have antedated his. Dr. Collins is now eighty years of age and is still in active practice.

The American Roentgen Ray Society will hold its fifth annual meeting at the Louisiana Building, 911 North Vandewater Avenue, St. Louis, on September 9, 10, 12, and 13, under the presidency of Dr. James B. Bullitt of Louisville, Ky. It has been arranged to have the sessions in the mornings only, the afternoons and evenings, as well as the intervening Sunday, will be reserved for general sight-seeing. The exhibit of apparatus will be held in the hall of the Louisiana Building. This will be especially important and interesting, giving the members an opportunity to inspect and familiarize themselves with the improvements and advancements of the past year. A Print Exhibit of much interest will be arranged in a room adjoining the exhibit hall. Arrangements have also been made for the exhibition of *x*-ray apparatus and the epidiascope in the German Section of the Educational Building at the World's Fair. A lantern, with competent operator, will be on hand and ready for use at any time. Those who desire to illustrate remarks need only bring the slides. The Grand Avenue Apartments, Grand Avenue and Morgan Street, will be the Official Headquarters. The secretary of the society is Dr. Russell H. Boggs, Empire Building, Pittsburg, Pa.

Smallpox in Illinois.—Dr. John E. Owens, chief surgeon of the Illinois Central Railroad, wrote the Secretary of the State Board of Health, Dr. Egan, under date of August 26, that there were cases of smallpox in houses opposite the Illinois Central Station at Centralia, and that his efforts to have the cases quarantined had failed. The railroad men threatened to quit work because of the incoming and outgoing of these people with smallpox. The Mayor of Centralia had failed to quarantine at his request. Dr. Egan immediately sent Dr. Baker to Centralia, who still remains on the ground until the disease is under control, and who will see to it that the cases are quarantined. There were sixty-eight cases of smallpox at East St. Louis during July, eight of which having terminated fatally.

Charges against a Hospital.—A complaint has been made to the State Board of Charities against the trustees and managers of the Sydenham Hospital at 339 East 116th street by four physicians who were formerly members of the medical staff, but who now ask that the charter be revoked. The complainants charge that they were made to pay for their appointments on the attending staff of the hospital a certain sum as a sort of initiation fee and a definite amount monthly. They also say that the institution has been conducted in "an unsanitary, unlawful, negligent, and improper manner." The managers deny the truth of these charges, and say that the members of the attending staff knew that the hospital was a charitable institution without endowment, and came in with the understanding that the money they contributed was to go toward the support of the hospital. One of the attending physicians who was dismissed has sued the chairman of the board of trustees for $50,000 damages.

Lectures on Hygiene at the New York School of Philanthropy.—The committee on philanthropic education of the New York Charity Organization Society has announced a partial list of the lectures and courses of the School of Philanthropy for the session of 1904-05. The school, opening on October 3, will continue in session until June 1, with holiday and spring vacations, and be followed by the summer school from June 19 to July 28. From the list of lectures published in *Charities* of August 27, we find thirty lectures devoted to hygiene, hospitals, and the prevention of disease, as follows: Silas F. Hallock, M. D., "The Use of Hospitals, Dispensaries, and Diet Kitchens," three lectures. Hermann M. Biggs, M.D., "The Scope and Function of the Board of Health," two lectures. William H. Allen, general agent, Association for Improving the Condition of the Poor, "Sanitary Aspects of Social Work," ten lectures. Miss Lilian Brandt, statistician, Committee on Prevention of Tuberculosis, "Social Factors in the Problem of Tuberculosis."

The Tri-State Medical Society of Alabama, Georgia, and Tennessee will hold its sixteenth annual meeting at Chattanooga on October, 12, 13, and 14, under the presidency of Dr. F. B. Sloan of Cowan, Tenn. Addresses will be made by Drs. William J. Mayo of Rochester, Minn., and A. J. Ochsner of Chicago. Information regarding the meeting may be obtained by addressing the secretary, Dr. Raymond Wallace, Loveman Building, Chattanooga, Tenn.

A Canteen Argument.—Two poor fellows of the Sandy Hook garrison have fallen victims to anti-canteen legislation in the army. They died from the effects of poisoning by wood alcohol, and the deaths are ascribed by officers at Fort Hancock to the abolishment of the post exchange. It is five miles of hot sandy road to Highland Beach, the nearest place where a drink can be had. Men who go that far for a drink will not be satisfied with one or two, but having so few chances, such is human nature, embrace the opportunity to get drunk. It was to allay the depression and thirst the morning after a visit to Highland Beach that these men drank some bay rum with fatal results. Both men bore good characters and had been in the service several terms of enlistment. Neither had been considered a heavy drinker before the post exchange was removed from the fort, four years ago.

International Amenities.—M. Waldeck-Rousseau, the French statesman, died recently of cancer. He was operated upon shortly before his death by Dr. Hans Kehr of Halberstadt, and the French medical journals are now asserting that his death was hastened by the operation and blaming the surgeon. Dr. Kehr replies to these attacks in the *Deutsche medizinische Wochenschrift* of August 25. He says the patient had absolutely no chance to recover without an operation, whereas an operation saves 34 per cent. of such cases. M. Waldeck-Rousseau, he says, had nothing to lose through the operation, since without it he had only a few weeks at most to live.

Dr. Robert Koch retires on October 1 from his post as director of the Institute for Infectious Diseases in Berlin. He will be succeeded by Dr. Gaffky of Giessen.

The California State Board of Pharmacy is undergoing a rigid investigation. Charges had been brought alleging misconduct, from official extravagance to partiality toward the students of one of the colleges.

A New Hospital at Orange.—The estate of the late Samuel F. Jayne and three adjoining lots in Orange, N. J., have been purchased by the rector of the church of Our Lady of Mount Carmel as a site for a new Catholic hospital. The building will face on Centre Street.

Dr. A. W. Dodd has been appointed District Physician in the First Ward, Cincinnati, to succeed Dr. Bateman resigned.

Bethesda Hospital Improvements.—The Bethesd a Hospital and Home for German Deaconesses, at Oak Street and Reading Road, Cincinnati, will be improved to the extent of $25,000. A chapel and additional sleeping apartments will be erected.

Suture of the Heart.—The patient on whom the operation of heart-suture was performed recently at Los Angeles died on the eighth day as a result of pericarditis. The wound in the wall of the heart was found to have made a perfect union.

Bacteriological Condition of Chicago Milk.—During the months of May and June, the laboratory of the Chicago Health Department devoted its attention especially to the bacteriological condition of milk, and the Bulletin of June 11 stated that "the directory reports that the laboratory has been making a thorough bacteriological examination of the milk supplied to the Chicago market, and finds that while the milk is usually up to standard as regards chemical constituents, the conditions from a bacteriological standpoint are not at all satisfactory. The average milk contains a far greater number of bacteria than is usually found in wholesome milk. The remedy of this condition lies not only in the careful handling of milk in the city, but also in the careful production and handling of milk according to sanitary regulations on the farm." The Department, therefore, immediately began an active effort to remove the cause, first, by prohibiting the sale of milk from cows that were fed on brewery slops or refuse from vinegar factories. Up to the present time the department has returned the milk to over one hundred shippers for this cause alone. They have been notified that they must either discontinue feeding "wet malt," or their milk will be returned or destroyed if shipped to Chicago. Of these hundred shippers, thirty have given affidavits to the effect that they have stopped feeding "wet malt" and will not do so again

Dr. Edmund J. James has accepted the Presidency of the University of Illinois. He was formerly President of Northwestern University. He will take charge of his new office November 1.

Rauch Park.—The late Dr. John H. Rauch was a wonderfully energetic and capable santitarian. For many years he was secretary of the Illinois State Board of Health, and it has been suggested that in selecting names for public parks for Chicago, his name be among those chosen, as he was said to be the father of the park system of that city.

Obituary Notes.—Dr. William Rice Pryor of this city died on August 25 in St. Vincent's Hospital, after a fortnight's illness, at the age of forty-six years. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1881. He was professor of gynecology in the Polyclinic, visiting gynecologist to St. Elizabeth's Hospital, and consulting gynecologist to St.Vincent's Hospital. He was a member of the American Medical Association, the New York Academy of Medicine, the American Gynecological Association, and the Southern Surgical and Gynecological Society. He wrote a "Textbook of American Gynecology," 1896, "Pelvic Inflammations," 1900, and a "Textbook of Gynecology," 1903. The funeral services were held in the Church of the Transfiguration on Sunday afternoon. The pall-bearers were Dr. Howard Kelly of Baltimore, and Drs. H. C. Coe, George T. Harrison, J. P. Tuttle, W. R. Townsend, and A. R. Robinson of New York.

Dr. Harriet E. Goodrich of Salem, Mass., died on August 23, at the Salem Hospital, as a result of head injuries received in falling from a street car. She was thirty-three years old and a graduate of Tufts Medical School in the class of 1900.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

CONGRESS SEASON—ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE, COMING MEETING—OXFORD ECHOES—MOSQUITOS AND COLORS—DEATHS OF SIR W. MITCHELL BANKS, SIR FREDERIC BATEMAN, DR. GILBART-SMITH, DR. G. HOLLOWAY, STAFF-SURGEON SCANLAN.

London, August 12, 1904.

We are in the full season of Congress and conferences. Two on sanitary matters have passed and but for the pressure of the Oxford meeting might have claimed more attention. The mother of these meetings, The British Association for the Advancement of Science, will soon be in session, and the Prime Minister will deliver the presidential address. This function has often given rise to prolonged press discussions, and the forthcoming meeting at Cambridge is not likely to lack in lively debate. Sir William Crookes said at one of these congresses that one member was in the habit of stating his views in the physical section, while other members stated exactly the opposite, and that each side, satisfied that their case could not be demolished, went away and let the matter rest for another year. Really this might be said of many another meeting of scientists, and—"take it not in Gath"—of doctors also. Among promised topics I may mention "World Weather" and the suggestion "that our meterological office should work with yours," "Heredity and Variation," "Housing of the Poor," and in the physiological section "Condition in Nerve Cells." A joint discussion of the zoological and botanical sections is to be held on the significance of the nuclear division of cells and the reduced number of chromosomes in relation to cancer. Radioactivity and the disintergration of atoms also offer scope for a renewal of controversy and a shoal of hypotheses.

British Medical items still occupy attention, especially of returned friends from Oxford. Some express pleasure with the sectional work and some, as usual, the reverse. One tells me his section was very poor—another pronounces his "stale, flat, and unprofitable." A third writes to me of the whole meeting, that it was "dull, uninteresting, and without focus." Yet another says of all the papers and discussions he heard none was above the average and several were under it. On the other hand, some speak and write of originality and value as characterizing their section. This is especially so with the tropical section, about which the majority are enthusiastic. The discussion in this section on trypanosomiasis was certainly the occasion of bringing out quite recent researches, and that on the Leishman-Donovan bodies was replete with still newer investigations. These two should have a special interest in America. So for that matter should the discussion on malaria, but in this there was little that your readers are not acquainted with

In the dermatological section Dr. Sequeira, who has charge of the Finsen light department at the London Hospital, opened a discussion on comparative value, new and older methods of the treatment. He considered *x*-rays and Finsen's method in lupus, rodent ulcer, epithelioma, etc., and pointed out the limitations of these plans as well as some indications for their employment. Dr. Hall-Edwards read a paper on *x*-ray dermatitis, and described what he had suffered personally from repeated demonstrations. The pain had been very acute, and his paper should be taken to heart by all who are working with these rays. It will be remembered that the injury they may cause has already been the subject of proceedings in our law courts. Dr. Whitfield opened a discussion on bacterial and other factors in the causation of skin diseases, a subject he illustrated by lantern slides.

Complaints have often been made as to the difficulty of inducing native races to adopt precautions against malaria, and West African sanitary authorities have asserted that Europeans do not take the mosquito theory seriously. Perhaps they think nothing will get rid of the pests, and so, considering their numbers, escape from a bite or two is impossible. Then there are discussions that the ordinary resident white man fails to appreciate. He smiles at the notion that mosquitos have taste in colors and hardly believes that the investigator who entered a tent in dark gray flannels was at once attacked, while another in white garments was avoided, or at least neglected. If white clothing is so obnoxious to mosquitos, why don't they let alone white faces, hands, etc.? The experiments in this direction are, however, interesting if not convincing. Boxes lined with various colored cloth were placed on the floor; mosquitos went into the blue in great numbers but fewer into other colors, and a sort of scale was established as follows: blue, dark red, brown, scarlet, black, slate, gray, olive, green, violet, leaf green, pearl, pale green, light blue, white,

and orange What artistic creatures these anopheles must be! Or did individuals display different tastes?

Profound regret was produced in Liverpool on Tuesday afternoon by the receipt of a telegram announcing the sudden death of her great surgeon, Sir William Mitchell Banks. He was spending his holidays on the Continent and died there from an attack of angina pectoris. He was born in 1842, educated at Edinburgh, where he took his M.D. with honors, gaining the university gold medal for an anatomical thesis. He was demonstrator of anatomy at the Glasgow University from 1865 to 1867, and then settled in Liverpool, where, as a surgeon and teacher, his reputation has ever since been growing. He devoted much time to the Royal Infirmary, to which he was surgeon, and to University College—now the Liverpool University—of which he was Emeritus Professor, and he took a leading part in the resuscitation of the medical school. He had been on the council of the Royal College of Surgeons and on the General Medical Council. You will not have forgotten his oration at the Medical Society of London (1892), nor his address on surgery at the Montreal meeting of the B. M. A. It was a treat to read any of his surgical contributions. He was knighted in 1899, and the same year received the honorary degree of LL.D. of the Edinburgh University. He was also a justice of the peace.

Sir Frederic Bateman, M.D., LL.D., of Norwich, died from a stroke of paralysis on Wednesday at the age of eighty years. His name will be familiar to you as the author of "Aphasia, or Loss of Speech and the Localization of the Faculty of Articulate Language," the essay which gained for him the Prix Alvarenga of the French Academy of Medicine in 1891. He was educated at Paris and University College, London. He took the French diploma of Officier de Santé in 1846. In 1849 he became M.R.C.S., Eng., and the next year M.D., Aberdeen. He was elected F.R.C.P. in 1870, his reputation having then been long established. He was physician for many years to the Norfolk and Norwich Hospital and on retirement elected consulting physician, besides which he was connected in the same capacity with most of the charities of the city and neighborhood. He was a fellow and laureate of the Paris Academy of Medicine and corresponding member of various foreign societies, especially those devoted to neurology. He was knighted in 1892 for his researches on aphasia. Besides his contributions to that subject, he also wrote "Darwinism Tested by Language," "The Idiot and His Place in Creation," and various articles in the journals, both English and French; some, too, in those of the United States.

Dr. Gilbart-Smith, F.R.C.P., physician to the London Hospital, died suddenly on the 3d inst., in his fifty-sixth year. He was on a bicycle ride with his son and two ladies, when he fell from his cycle and died almost immediately from heart failure. His son went to the nearest town, five miles, for assistance, leaving the two ladies with the corpse, and during his absence there was a heavy thunderstorm. The inquest was held on Friday; verdict heart failure, and the body was brought to London that evening. Dr. Gilbart-Smith was appointed assistant in 1878 and became full physician to the London Hospital in 1894. He was a T.C.D. graduate, M.B. 1869, and M.D. 1873. The Irish Medical Graduates' Association lose in him its president and the London Hospital a greatly respected teacher and students' friend and guide.

Dr. William George Holloway, surgeon to the Central Throat Hopsital, has died at the early age of forty-three years. He took first class in the Natural Science Tripos at Cambridge, 1883; M.B. 1888, and M.D. 1890. He had meantime studied at St. Mary's Hospital, where he was also a prizeman.

Henry Scanlan, M.B., staff surgeon, R. N., retired, died on the 31st ult., aged fifty-five years. He entered the navy in 1872 and became staff surgeon in 1884, when he went to the Soudan and earned the medal with clasp and the Khedive's bronze star. He was retired in 1885.

Capillary Pulsation in Urticarial Wheals.—George Carpenter writes that urticaria in early childhood is one of the most common ailments, but capillary pulsation in the wheals is a decidedly unusual feature. He describes the case of a small boy of two and one-half years, who suffered with marked urticaria of one day's duration. The wheals were large and prominent, and many of them were surmounted by a diffused and clear exudate. Some were capped by tense bullæ. Capillary pulsation was a prominent feature in the various lesions, and factitious urticaria was observed.—*The British Journal of Children's Diseases.*

OUR VIENNA LETTER.

(From Our Special Correspondent.)

PHARYNGEAL TUBERCULOSIS—CARDIAC ARRHYTHMIA IN CHILDHOOD—AN ACID-PROOF BACILLUS FOUND IN A PECULIAR DERMATOSIS—WEIGHT TREATMENT OF PELVIC ADHESIONS—THYROID EXTRACT IN CRETINISM—RETIREMENT OF PROF. VOGEL—MONUMENT TO KAHLER.

Vienna, August 6, 1904.

At a recent meeting of the Society for Internal Medicine and Pediatrics, Dr. Bela Schick demonstrated a case of pharyngeal tuberculosis in a boy of thirteen. The child, who had previously seemed perfectly healthy, was brought to the Escherich Clinic complaining of sore throat. Upon admittance an examination of the pharynx showed a yellowish-gray membrane, 1.5 cm. long and ¾ mm. wide, beginning at the root of the uvula and extending along the edge of the posterior pillar of the fauces on the right side. The membrane was very adherent and slightly raised above the level of the mucosa, which showed no reactionary reddening. Scattered over the posterior pharyngeal wall were found numerous small patches, some of which attained the size of a pin head. A smear taken from the membrane showed tubercle bacilli. The glands of the neck were much swollen and there was moreover, a distinct involvement of the apex of the left lung. The case was the more interesting, because a sister of the patient also showed symptoms of pharyngeal tuberculosis, so that a family predisposition toward tuberculous affections of the pharynx may be assumed.

Professor Escherich presented a case of idiopathic arrhythmia of the pulse in a child of nine years. The boy, who was admitted to the hospital suffering from diabetes insipidus, showed an irregularity of the heart's action which remained unchanged during the two weeks he spent at the hospital and manifested itself in the form of occasional intermittences, which were especially noticed when the pulse was infrequent, and disappeared when the pulse became rapid. The affection might easily be overlooked during a hasty examination. According to Escherich's experience, arrhythmia of the pulse is a very frequent occurrence in childhood, being in most cases a symptom of some morbid condition and disappearing with the cure of the disease.

Before the Budapest Royal Association of Physicians Prof. S. Rona reported on an acid-proof bacillus which he had found in a peculiar skin lesion. The patient, a driver, thirty-four years old, had suffered for a year from a most peculiar skin affection which took the form of a disseminated folliculitis, perifolliculitis, furuncles, and phlegmons, in connection with cutaneous suppuration. It was at first believed to be a staphylococcus infection; later, as suggested by the occupation of the patient, an infection with the bacillus mallei. Bacterial examinations, however, were negative. In the pus of a subcutaneous lesion great numbers of an acid-proof bacillus were found. Animal experiments for tubercle bacillus were negative, and the author assumed that the peculiar cutaneous affection was caused by this acid-proof bacillus. Morphologically and biochemically the organism strongly resembled the tubercle bacillus, and the histological changes corresponded with those found in tuberculosis.

Dr. Arthur Foges not long since read a paper on "Some New Methods of Gynecological Treatment" before the Vienna Association of Physicians. He said there was now a more conservative tendency in the treatment of inflammatory affections of the female genital apparatus, the main reason being that the radical removal of the adnexa was not an indifferent matter to the individual. In case of a collection of pus in the adnexa, their complete removal is probably indicated. On the other hand, the various forms of pelvic peritonitis which remain after acute inflammations of the genitalia (puerperal infection, ascending gonorrhœa, etc.), offer a fine opportunity for the employment of conservative therapeutic measures. The Thure-Brandt method of pelvic massage has for some time been used to stretch or separate such inflammatory adhesions, but it is surpassed in efficiency by the weight treatment. The chief indications for the use of this method are peritoneal adhesions in the small pelvis, following gonorrhœal, puerperal, or appendicular inflammations or operations. In many cases a marked subjective improvement was noticed after a few treatments, the weight in the vagina being gradually increased from one-half to one kilogram. The objective improvement did not keep pace with the relief experienced by the patient; in more than one-half the cases the adhesions were palpable in Douglas' cul-de-sac, even after repeated treatment, but these had wholly or in great part lost their tenderness. In retroversion and flexion of the uterus, complete replacement was impossible in seven out of eight cases, but subjective improvement was marked,

and any fresh disturbances were temporarily relieved by two to three repetitions of the treatment. The weight method also acts very well in cases of movable retroflexion, retroflexion of the gravid uterus, parametritis, for the stretching of painful cicatrices or cicatricial contractions of the vagina. In cases of chronic inflammation of the adnexa, the weight treatment must be cautiously employed, since it may set up an acute exacerbation; the slightest rise in temperature must serve as a warning to discontinue the treatment. In cases of chronic inflammatory swelling of the adnexa or the pelvic cellular tissues, abdominal weights in the form of sand or shot bags weighing one-and one-half to two kilograms are used in addition to the weights in the vagina. The speaker had had good results with Apostoli's method in five cases of endometritis and climacteric hemorrhages. The current must be turned on and off gradually; for an active intrauterine electrode the speaker used a platinum or aluminum sound, and for the inactive abdominal electrode he employed a piece of sheet zinc wrapped in a moist compress. In eight cases of marked prolapse in old patients who had refused operation, good results were obtained by the use of Rosenfeld's stem pessary.

The publication of Professor Wagner's experiments on the cure of cretinism has aroused widespread interest. Four years ago, at a session of the Health Board of Lower Austria, Professor Wagner advocated that this body request the Ministry of the Interior to conduct, officially, experiments on the treatment of cretinism with thyroid extract. The Chief Sanitary Council unanimously supported him and further steps were taken in the matter by the Board of Health. The experiments were very successful and lead us to hope that a cure of this endemic disease may eventually be found. Cretinism is very frequent in our Alpine provinces and occurs, though less frequently, in Switzerland, Savoy, and Piedmont. In the Pyrenees also we meet individuals who show all signs of a physical and mental degeneration. Thyroid extract is found to stimulate the dwarfed bodies to growth. Persons beyond the age when growth ceases normally began to gain in height; at the same time they lost fat, the pendulous abdomen disappeared, the cheeks seemed less puffed up; the goiter also underwent retrograde changes, proving that the degenerated thyroid gland changed into one with healthy functions. The mental effects which Wagner reports were phenomenal. Children treated by his method became more lively and active. They began to play, their curiosity and their imitative faculties were aroused. They showed an interest in the work and occupation of adults, they began to talk, their hearing improved, they learned to sing. A few of the little patients were enabled, by continued treatment, to attend school, and showed a certain desire to learn, while previously they had avoided all mental exertions. These are very important results, for the number of cretins in our Alpine provinces is estimated at 40,000. Even though Professor Wagner's treatment cannot make all of them healthy, it can certainly bring thousands back to a useful life.

Last month the well-known pharmacologist Professor Ritter von Vogel retired from his position in the university, owing to his advanced age. Numerous ovations were tendered him, and on the occasion of the farewel dinner the eminent scientist was presented with an artistic placque bearing his portrait and with an address setting forth the great services he had rendered to science.

On the same day another celebration took place at the Vienna University—the unveiling of a monument to Prof. Otto Kahler, who succeeded Dr. Bamberger at the university. Unfortunately, he worked here for but a short time, since a sad fate cut short his career and darkened his mind, the eminent physician and investigator dying insane in 1893. His foremost pupil, Dr. Kraus of Berlin, delivered the memorial address, and Professor Nothnagel spoke in heartfelt words of the achievements of the deceased.

The Relative Efficiency of Surgical Dressings.—McGregor and Ramsey have undertaken experiments to determine the relative absorbent power of surgical dressing materials. Their conclusions are: (1) The most suitable drainage material for the conveyance of fluids with iodide in suspension is dry boracic lint; cellulose wadding is almost as efficient, but more friable, unless enclosed in gauze; (2) The best covering materials for facilitating discharge from the distal end of the drain are cellulose wadding and gauze; the covering material should be sufficient to act as long as the drain; as the blocking of the drain takes place in four to eight hours, a more frequent dressing than usual is required.—*British Medical Journal.*

Progress of Medical Science.

Boston Medical and Surgical Journal, August 25, 1904.

The Practical Application of Hydrotherapeutic Measures.—Charles S. Millet advises us to keep in mind the facts that hydrotherapy has to do with sensation, excretion, and heat radiation, in order that we may find its application easy. By applying water to the skin at various degrees of temperature, and in various ways, we can, by reflex action, produce decided effects upon the mind, the central nervous system, and the internal organs. Whether to use hot water or cold in fever depends on the pulse; if it be of high tension, full in volume, and the skin hot, a cold bath will give the best results. The sponge bath may be used for slight febrile conditions; if severe, the tub bath is most useful, accompanied by friction and cold to the head. The temperature may be reduced gradually from 100° to 90° in ten minutes. This is excellent for children, but water should be used colder for adults. It is important to secure a good reaction after the bath. In melancholia or acute mania the patient may secure good sleep by the use of a hot bath, with a pail of cold water thrown suddenly over the shoulders while sitting in the tub. In kidney diseases the hot pack is most useful, followed in chronic cases by a short, quick, cold affusion and rubbing. In chlorosis, anæmia, chronic pulmonary, and organic heart diseases, perspiration should be first produced, and then a warm shower, followed by a cold shower given. Locally heat and cold act just as they do on the whole body. Ice is the best substitute for opium.

Journal of the American Medical Association, Aug. 27, 1904

Linear Nævi.—M. L. Heidingsfeld states that linear nævus is a dermatological affection, for the most part easily recognized as a type, *sui generis*, possessing an unmistakable identity. Great variations in clinical appearance, location, duration, development of secondary changes, have permitted an endless amount of unnecessary redundant nomenclature. It also possesses an exceedingly varied pathology. Great disparity in histological structure exists between lesions that are clinically similar; great disparity exists between lesions in close proximity from the same patient; a deceptive histological resemblance often exists between lesions of linear nævi and types of dermatological affections totally different in character. The affection aptly illustrates some foibles of present-day dermatology, namely, the tendency to individualize and thereby complicate, rather than generalize and thereby simplify single types in classification; and secondly, to give to dermatological pathology an inflated diagnostic rather than a mere confirmatory value.

A Case of Tetanus Treated by Subdural and Intraspinal Injections of Antitoxin.—C. W. Wille reports such a case. The points of interest to be noted are the short period of incubation, which was exactly five days; the extreme rapidity of the disease—forty-two hours—the marked involvement and apparent selection of the lumbar spinal and abdominal group of muscles, and the comparative freedom from involvement of the muscles of the limb through which the tetanus organisms and toxin made their entrance. The negative evidence deduced from this case would advise an early recourse to the use of antitoxin administered subcutaneously or along the sheath of the nerve trunk supplying the injured location as a preventive measure, or subdurally or intraspinally as a curative procedure.

A Case of Carbolic Acid Gangrene.—E. Dunster Kremers reports the case of a schoolboy, fifteen years old, who had always been strong and healthy. On July 4, 1904, he cut his little finger with a piece of glass, and because there had been a case of tetanus in the town the boy's sister, on the morning following the injury, applied a rag soaked in carbolic acid solution, three drops of the liquefied acid being added to fifty drops of water. Twenty-four hours later the rag was removed and the patient thought it was not strong enough and accordingly applied a stronger solution and the bandage was applied very tightly. The next morning the finger looked very white and was massaged. On July 8 the doctor was called, who ordered a wash of boracic acid, hoping to restore the circulation. On July 11 the finger was black and began to be tender. On July 13 the patient went to bed with evident fever. The finger was now entirely bluish black and had a well-marked line of demarcation about one-half an inch below the metacarpophalangeal joint. Above this there was a line of redness and swelling. Under chloroform anæsthesia the finger was amputated at the metacarpophalangeal joint. No pus was found and a healthy flap was secured. The wound healed by primary intention. Urine examination was negative. The strength of the solution used in this case was probably about 5 per cent. It was applied for

about twenty-four hours and caused no pain or discomfort. The tight constriction of the finger undoubtedly assisted in the production of the complete gangrene.

Medical News, August 27, 1904.

Need of More Accurate Knowledge in the Diagnosis and Treatment of Chronic Suppurative Otitis Media.—James F. McCaw believes that many die from intracranial complications in which chronic suppurative middle-ear disease is never recognized as the cause. The disease progresses insidiously, destroys the delicate structures of the middle-ear, invades the bony walls, impairing their nutrition, and ends in caries or necrosis. The symptoms often progress without much pain. The nose and nasopharynx should receive careful attention early in the disease. Then free drainage should be established, if necessary by enlarging the opening in the drum membrane. A perforation high up in the drum usually signifies necrosis of the ossicles, or involvement of the attic structures. Polypi and granulations should be removed, and cholesteatomatous changes or involvement of the mastoid call for radical operation at once.

Delirium from Nervous Shock.—Pearce Bailey gives clinical examples of the character of the symptoms, and the variations in their severity, which result from nervous shock in presumably normal persons. The mental symptoms are essentially delirious. They vary from slight and transient attacks of mental confusion to profound disturbances of consciousness with the physical symptoms entailed thereby. The outcome may be complete and perfect recovery, or recovery with defect, or the symptoms may become progressively worse and end fatally. When the result of injury, this psychosis may appear immediately or may succeed by a few days the unconsciousness due to the injury. In symptoms it can hardly be distinguished from delirium of other origin. Nervous shock, from sudden fright, grief, or remorse, and perhaps even joy, may be the determining source of such symptoms. Hysteria and neurasthenia are the neuroses in which emotional causes figure most prominently. In insanity emotional factors operate commonly in producing the attack. The pathology of delirium from nervous shock is entirely speculative; at the same time, in the cases that have ended in autopsy, there have been found evidences of disturbed circulation. Fright causes the blood to leave the surface of the body, there are then different effects, such as tachycardia, or slow pulse. A fall in blood presure follows the initial rise. Traumatic delirium is probably due to change in blood pressures.

New York Medical Journal, August 27, 1904.

Status Lymphaticus and Death Following Chloroform Anæsthesia.—Frederick A. Simmons, having noted the frequent incomplete reports of death due to chloroform anæsthesia, and references to the possibility of existing lymphoid diathesis in patients thus dying, reports a case which is particularly interesting, in that it presents a thorough investigation of a death from chloroform, such records being rare. At the time of death status lymphaticus was suggested as a possible cause, and it is interesting to note that literature upon this subject presents conditions closely allied to the autopsy findings of the case reported, the present definition of status lymphaticus being "a so-called constitutional disorder characterized by a persistence or hyperplasia of the thymus, and by general lymphadenoid hyperplasia, frequently associated with cardiac and arterial hypoplasia, and the osseous evidences of rachitis."

Multiple Sarcoma of the Subcutaneous Tissue, without Evidence of a Preceding Primary Growth.—T. Turner Thomas reports such a case occurring in a man eighty years old. In an analyses of 2,515 cases made by Picot, Williams, and Gurlt, to establish the initial seat of the disease, not one was shown to have begun in the subcutaneous tissue. In the history of the cases reported, there was nothing elicited pointing to any other than the first tumor which was noticed in the subcutaneous tissue. In the absence of evidence of primary tumor, the diagnosis is not always easy; such tumors may be mistaken for tuberculosis, syphilis, or other conditions not distinctly inflammatory. The advanced age of the patient was worthy of note, because sarcoma occurring in senile tissue is very rare. The tumors apparently did not begin and spread in the skin, nor did they originate in the hands and feet, and spread toward the trunk. In the case reported there was nothing suggesting eczema, erysipelas, or anything inflammatory, no ulceration, and nothing of the fungoid, or mushroom appearance. There were but few pigmented areas. Regarding treatment, little can be said. When primary sarcoma of the skin is seen early, it should be excised freely, but it should not be forgotten that excision of such tumors has been followed by a more malignant course of the disease. Suspiciously active moles should always be excised early.

Facts and Arguments for and against the Infectious Nature of Malignant New Growths.—Charles H. Richardson, after reviewing the history of the germ and the cell theories of cancer, and noting the results of observations and experiments of investigators, concludes that the various mentioned so-called parasites fail to make good in fulfilling the requirements of an infective agent; but, according to competent authorities, are changed or degenerated cells, not thoroughly classified. Contaminations could not be excluded in the few cases that showed any growth out of the vast number of cultures taken on every known media. The tumors produced by inoculation of blastomycetes show them to be only granulomata; blastomycetes can be cultivated from the air, and hence, contamination is always possible. In short, it is true that no one has so far been able to grow or demonstrate parasites in malignant growths. The facts and arguments are so overwhelmingly on the side of embryonic theory, that for the present at least, we shall have to believe that malignancy is due to an abnormal play of forces within the body of which we, as yet, know but little. He believes that time will show a reaction in the present movement of parasitism, and many of its strongest advocates will refute their theories and admit that their conclusions were reached without sufficient investigation.

Röntgen Rays in the Treatment of Tuberculosis of the Joints. J. Rudis-Jicinsky states that the *x*-ray will not only absolutely diagnosticate tuberculosis of the joints in the earliest stage, show the smallest tuberculous focus developing in the spongy tissue of the bone near the epiphysis, or any extension of the destructive process toward the surface of the joint, or perforation of the joint by the focus, or the inception of tuberculous synovitis, but will show the effusion by dark and marked shadows. He relates a number of typical cases in which he has had remarkable cures as the result of the *x*-ray treatment. He applies the proper support to the joint so that it will become ankylosed in about four months. In simple tuberculous synovitis he injects the joint only once with iodoform emulsion, formalin, and glycerin and exposes it immediately to the *x*-ray. In children, exposures were given daily for five minutes in the beginning, up to ten minutes later with a low vacuum tube; in older patients he employs a high vacuum tube, at a distance of from six to eight inches. This treatment does not prove successful in cases of tuberculosis of the hip-joint and spine. When we find albumin in the urine, a peculiar itching in the exposed joint, and profuse sweating of alkaline reaction, the ray must be stopped for a few days. Further investigation, more thorough technique, and standard doses should produce better and more uniform results in radiotherapy.

American Medicine, August, 27, 1904.

Torsio-hæmatocrit and Centrifuge.—Henry Emerson Wetherill describes an improvement on the hæmatocrit which renders it possible to determine more rapidly the amount of blood cells. The quantity of chemical precipitate can be determined in urine, milk, sputum, etc., and suspended solids can be determined quantitatively by means of it. The instrument is scientific, mechanical, and low priced, and the determination can be made at the bedside. The whirligig principle applied by jewelers in bow drilling is used in its construction. The speed is much greater than in the hæmatocrit. The double motion of the tube gives less precipitate on one side of the tube, as the corpuscles are thrown down in a zigzag course to the outer end of the tube. The author calls his instrument the torsio-hæmatocrit.

A Case of Large Fibromyxosarcoma of the Sacrum, Successfully Treated by Cataphoric Operations.—G. Betton Massey reports a case of large tumor of the sacrum in a woman of twenty-six, who had had two difficult labors, followed by a normal one. The tumor was the size of two fists, behind the rectum, and attached to the inner surface of the sacrum by a broad base. It was growing rapidly. The patient was anæsthetized and placed on a negative pad on a cot. An incision was made over the upper part of the coccyx and a sharp pointed zinc-mercury electrode was introduced and thrust through the healthy tissues about the coccyx into the tumor, so as to avoid injuring the sphincter ani. A current of 1600 milliampères was slowly turned on, which developed the ionized chemicals by electrolytic destruction of the anode, and dispersed them radially from the electrode, necrosing and sterilizing an increasing area of skin, subcutaneous tissue, and malignant growth. The current was used for three hours. The necrosed area covered three inches. Twenty-one days later, three of the bones of the coccyx and one-half of the tumor sloughed out of the opening. Another application of electricity caused the remainder of the tumor to come away. The recovery was slow, but resulted in the entire removal of the tumor, with a useful rectum and a very small sinus.

Treatment of Chronic Colitis.—Jesse Shoup includes all forms of colitis under one head, and applies the same treatment. Most cases of colitis occur in women, and are accompanied by gastroptosis, enteroptosis, or nephroptosis. The author believes that improperly prepared chyme entering the intestines, causes irritation, and inflammation, ending in chronic colitis. He supports the organs by a corset that is put on lying down, and laced from below up. He sums up the treatment as follows: (1) Treat the attack of pain which precedes the passage of mucus by a hypodermic of morphine and atropine, and promote thorough evacuation of the bowels by large doses of castor-oil by the mouth, and high enemas of oils or of alkaline solutions. (2) A carefully selected diet to suit the individual case, after a chemical examination of the stomach contents has been made. (3) Assist digestion and allay fermentation. (4) Keep the bowels open by means of oils by the mouth, which have the double office of laxative and lubricant. (5) Apply suitable support to overcome any ptosis of the abdominal organs. (6) Apply local treatment by means of astringent enemas and oils, and tropical application of the same when necessary. (7) See that the patient gets sufficient rest in the recumbent position, and when practical a change to the air of the mountains or seashore.

The Lancet, August 13, 1904.

The Value of the Addition of Citrate of Sodium to Cow's Milk in Infant Feeding.—F. J. Poynton, in his summary, states that the use of citrate of sodium offers certain advantages in that it renders the curd of cow's milk more easily digestible; that it is cheap; that it is convenient to handle, easy to control, and progressive in principle; that it allows the milk to be given in a more concentrated form, and thus avoids to some extent the dangers of underfeeding; that there is no danger of scurvy; that given as a medicine it gains the confidence of the mother. The indications are as a routine for weaning a healthy infant on to cow's milk, and for correcting milk dyspepsia. The drawback is a tendency to constipation, which is, however, easily controlled. The limitations are in rare cases of complete intolerance of cow's milk; in severe cases of gastroenteritis from impure milk; in organic disease, such as congenital hypertrophic stenosis; in very intractible cases which have been subjected to all sorts of different methods beforehand. This limitation needs more investigation. If he was asked for a routine method for the artificial feeding of the poor child he would say: First try citrate of sodium in the milk, provided the milk is sound.

"Interrupted Circulation" as a Therapeutic Agent.—William Ewart illustrates this by two cases of rheumatoid arthritis. He states that good effects have been derived from a continuous passive hyperæmia induced by slight compression of the veins above the part affected. The principle of treatment described has a wide range of application to the various tissues, including the extravascular tissues. The forces used are intensified by rapid alternations of capillary flushing, and of capillary emptying. The tourniquet is applied intermittently and sufficient pressure is used to close the arteries after draining the limb by elevation and stroking. The simpler view seems to be held that the emptied arteries suddenly receive a ramming charge when the tourniquet is removed, and that the internal surface of the capillaries, and of the lymphatic spaces in which they are immersed is subjected to sudden stimulation; whilst, on the other hand, during the preceding stage of ischæmia a certain amount of suction must have existed within them not only owing to the collapse of the elastic tissues, but also from the intravascular negative pressure set up by the procedure. The tendency would be for the emptied blood-vessels to suck up some of the remaining tissue lymph, or in case of inflammation some of the more fluid inflammatory exudates. In both the cases reported the synovial and lymphatic effusions appeared to have been benefited more largely than the periarticular fibrosis. The method was especially promising in the early stages, and in the exudative forms of rheumatoid arthitis.

Infective Cyclitis So-called Sympathetic Ophthalmia.—H. Percy Dunn emphasizes his belief in the possibility of infective cyclitis becoming an almost unknown disease, or of remaining in so modified a form as to cause but little anxiety either to the surgeon or the patient. By our acceptance of the infective theory, although it still lacks bacteriological confirmation, we are, nevertheless, placed in a position of knowing how successfully to avert and combat the disease, a disease which by its virulence in former days consigned so many hapless patients to absolute blindness. Possibly a specific organism of infective cyclitis may never be isolated, and the failure to isolate it may be explained by the incompleteness of bacteriological technique. The conjunctival sac may be described as the dumping-ground of the host of microorganisms which are met with in the human body. Apart from those which it receives from without, it is well supplied by cultivations from the nose and lacrymal sac, not to mention the possibility of another source of supply as furnished by disease of the neighboring bones and inflammation of their sinuses. In view of the conjunctival sac forming so favorable a medium for the cultivation of such complexity of microorganisms, and the impossibility of sterilizing it, the wonder is not that a disease of the nature of infective cyclitis should occur, but that any intraocular wound or operation should escape septic contamination. The probability is that the best course to pursue is to rely more on the mechanical removal of the microorganisms than on any attempt to insure complete sterilization of the conjunctival sac; it is, then, for this reason that after each step in any intraocular operations the wound is thoroughly douched with a 1 to 4000 solution of chinosol.

The Lancet, August 20, 1904.

The Medical Treatment of Deep-seated Hemorrhage.—Francis Hare reports five consecutive cases of hæmoptysis occurring in four patients which were stopped instantaneously by the administration of amyl nitrite inhalations. Hemorrhage depends essentially upon the existence of a certain blood pressure in the bleeding area, and the indication for medical treatment consists in reducing this localized blood pressure, and this might be achieved by promoting vasoconstriction of the arterioles supplying the bleeding area, or by promoting fall of blood pressure through widespread vasodilation in other areas. It is to the latter that he directs his attention.

A Case of Intestinal Obstruction after Gastroenterostomy.—H. M. W. Gray reports the case of an unmarried woman, thirty-one years of age, upon whom a posterior rectocolic gastroenterostomy had been performed, sutures alone being used. Seven days later intestinal obstruction was diagnosed and operation performed. It was found that practically the whole of the small intestine had insinuated itself from left to right through the ring formed at the first operation by the peritoneum of the under layer of the mesocolon, that lining the posterior wall of the abdomen and forming the upper layer of the mesentery, and completed anteriorly by the gastrojejunal junction. It was easily pulled back and the ring closed by suturing the under layer of the mesocolon to the upper layer of the mesentery to prevent recurrence of the hernia. There was enormous distension of the colon with gas. It was found to be quite patent down to the rectum. It was punctured by a trocar and cannula and the gas liberated. He could find no record in the literature on gastroenterostomy of such a post-operative condition.

The Respiratory and Cardiac Reflex Induced by Peripheral Impressions on the Pudic Nerve During Anæsthesia.—Alexander Wilson refers to Macewen's statement regarding the familiar spasm of the glottis produced during anæsthesia by forcible dilatation of the sphincter ani irritation on the parts supplied by the pudic nerve, and says that this spasm is part of an expulsive effort. The causes which give rise to it are of a kind which in normal circumstances tend to initiate expulsive efforts, and chief among these is any sudden increase in the intraabdominal pressure, as from distension of the bladder or rectum, etc. During narcosis normal stimuli conveyed to the nerve centers by a distended bladder or rectum or abnormal stimulation by forcible dilatation of the sphincter ani or irritation of the pudic nerve result in an expulsive effort. The completeness of this effort depends upon the degree of narcosis. It is interesting to note that forcible dilatation of the sphincter ani has been suggested as a remedy in chloroform accidents, the object being to stimulate respiration; it is questionable if at any stage of narcosis other than a very slight one this almost involuntary inspiration could be elicted by dilatation of the sphincter ani.

Electrocution on the Railway; Dangers of the Live Rail.—Thomas Oliver says that it is quite apparent from the number of accidents which have already taken place that a sufficient protection is not afforded the public against the dangers of the electric traction. For the distribution of electricity into town two kinds of currents are employed, the continuous, which at high tension causes burns and considerable disorganization of tissues and which, when severe, nearly always causes death, and the alternating which causes less severe burns while the destruction of the tissues is both less severe and not so diffuse. He refers to the experimental evidence that has been published during the past few years and then considers the voltage required to kill, regarding which opinions differ. As Professor Fleming states, "You may stand on a live rail or even sit or lie on it. . . . There is no danger so long as you are entirely on the rail. If you could be absolutely insulated from the earth there is probably no pressure of current that

would do you any harm. The danger comes when one part of you, especially a bare part, such as the hand or face, touches the live rail and some other part is in contact with the earth. That is where the 'live' rail constitutes so grave a danger." The manner in which this rail should be protected is a matter for electrical and railway engineers. After removing the victims of electrical shock from contacts artificial respiration should at once be resorted to and maintained for a considerable period of time. In addition Cunningham recommends transfusion of defibrinated blood.

British Medical Journal, August 20, 1904.

"First Aid" in Civil Life in the Tropics, as Illustrated by Indian Experience.—T. H Hendley uses the words "first aid" in their fullest sense, as including some instruction in the elements of sanitation, hygiene, and the prevention of accidents and disease. In so large a country as India, where there are so few well-instructed physicians that the natives are often from thirteen to twenty miles from any physician, and where they are themselves so ignorant of hygiene and physiology, it often happens that great suffering and even death result in cases of injury and disease that are capable of prevention by the layman. The author advocates, and has to some extent been able to secure, the education in "first aid" of government officials, police and constabulary officers, and even of the more intelligent class of natives. He believes, also, that the instruction of the young in schools is of the first importance. Volunteer women, as well as men, can also be trained. He advocates giving such a moderate amount of instruction as can be easily and safely acquired by persons of ordinary intelligence. Instruction in ordinary cleanliness is of the first importance in surgical cases. During the twenty-five years of the author's service he was able to instruct the public vaccinators, who in the summer acted as dressers in the hospitals, thus learning simple surgical methods, as well as the need of the trained assistance of a physician as soon as practicable. "First aid" in the treatment of domestic animals was found of great service in gaining the confidence of the natives. A simple manual was also arranged, with illustrations suitable to the country. A good deal of valuable training has been accomplished among the police, railway employees, and among youths in institutions of learning. Even slight knowledge is better than none at all, and although there may be mistakes, the risk of injury is slight.

Deutsche medizinische Wochenschrift, August 11, 1904.

Diagnosis of Typhoid Fever.—Kurt Walter, as the result of extensive trials of all the adopted methods, in military medicine particularly, concludes that the agglutination phenomena form an efficient aid to diagnosis, but must be applied with caution and cannot be considered as a substitute for the direct demonstration of the typhoid bacilli. Among the macroscopical methods, that proposed by Ficker is the most reliable in ordinary practice, but for scientific results, the microscopical procedures must still be applied. Ficker's method, however, affords a ready means of making use of the advantages of the agglutination phenomena for diagnostic purposes, without resorting to bacteriological laboratories.

Diabetes Insipidus Treated with Strychnine Injections.—B Leick reports an instance of the development of this disease in a man of forty-nine, previously in good health, after a fall which was accompanied by severe shock to the central nervous system. Other methods of treatment being without results, the author guided by the experience of Feilchenfeld in a similar case, began the injection of strychnine nitrate, in doses of from .0025 to 0.005 gm. daily for twenty days. The urine decreased in amount from 8000 c.c. Symptoms of intoxication by the drug prohibited its further use for a time, but the urine continued to decrease in amount down to 2400 c.c The other symptoms also improved, and at the end of four weeks the patient was practically cured, the urine being about 2000 c.c. in amount. The specific gravity, however, remained the same, 1005, throughout the treatment The author offers no explanation of the action of the remedy in this disease.

Treatment of Chronic Urethritis.—H. Lohnstein comments on the value of gradual dilatation in treating old urethral strictures, and describes an instrument devised by himself by means of which is not only the stretching of the stricture accomplished, but the urethral follicles are also emptied. The instrument consists of a metallic catheter, provided at one end with two windows through which can be made to project blunt currettes. The angle of the latter to the tube can be regulated by a screw arrangement at the distal end of the instrument. The writer claims that by this means every section of the urethra may be reached, and not only the follicles emptied, but proliferations on the surface of the mucosa removed, and constricting bands dilated. The method of application is like that used in the case of the ordinary dilators, but the effect is secured by a sort of rocking motion after the currettes are expanded. It was used in twenty-six cases with great success.

The Present Status of the Neuron Theory.—A. Bethe believes that recent research has shown that the neuron theory as first advanced, is no longer tenable. Certain facts may now be entirely denied and well marked doubts may be brought forward against the others. It is claimed that the neuron cannot be considered a cell unit, because later findings in development and histology, and also the demonstration of autogenous regeneration, show that at least the axis cylinders of the peripheral nerves are of multicellular origin. It is probable that in addition to the neuron complexes, there are other nerve elements, genetically independent of the former. In every nerve plexus, as found both in vertebrate and invertebrate animals, the cells are connected together by well marked anastomoses. In the central nervous system of the snails and crustaceans, fibrillary connections between the individual neurons can be demonstrated with certainty. In vertebrates such connections are not definitely proved, but sufficient evidence is at hand to make it quite certain that they are present. The author claims in conclusion that the neurons do not represent trophic units, much less functional ones. The name may, however, be retained and applied to the complex of ganglion cells, dendrites, and cylinder process. This term, however, should be limited to the idea of a teaching scheme and nothing more.

Berliner klinische Wochenschrift, July 25, 1904.

Progressive Inoculation from a Chimpanzee Infected with Syphilis.—O. Lasser published an account several months ago of a successful inoculation of a chimpanzee with syphilis and now presents a further communication in which he claims to have succeeded in inoculating a second member of this species from the first. The eruption was in the form of a generalized papular syphilide. A number of excellent pictures are submitted. The animal died shortly afterward of miliary tuberculosis and then the existence of the papules could be verified post mortem. Lasser believes that this experiment demonstrated conclusively that infection of the higher apes is possible, and that this animal may serve as a "test object" for the syphilitic virus and also permit of the production of a specific serum.

The Hæmolytic Action of Sublimate.—Detre and Sellei claim, as the result of their experiments, that corrosive sublimate acts as a poison to the red blood cells and, in a definite concentration, produces hæmolysis. Strong solutions fix the red cells, weak solutions dissolved them only partially or not at all. The degree of hæmolysis is dependent upon the time of action and the temperature. The blood serum protects the red cells depending on the amount present. The protective action disappears only when the temperature of the serum reaches 80° C., and the resulting coagulation does not afford any protection. Treatment with ether or alcohol detroys the protective power of the serum, but this faculty is then transferred to the ether. The authors conclude that the statement that the hæmolytic action of the sublimate on living protoplasm is brought about by the presence of lecithin.

Berliner klinische Wochenschrift, August 8, 1904.

Polymyositis in Measles.—Jessen reports a case of interest, in which a woman of thirty-two, who was taken ill with measles, developed on the sixteenth day a condition which was diagnosed as articular and muscular rheumatism, but later defined as an acute polymyositis. This was accompanied by a severe dermatitis. The patient made a very slow recovery. Such cases are rare and the etiology in this instance is of interest—no other cause could be assigned aside from the measles. Aside from instituting diaphoresis, the only remedy which had any effect was a 10 per cent. ichthargan ointment.

Treatment of Rhinoscleroma.—Begrow thinks that among the methods for treating this condition, decortication is preferable to excision, either partial or whole. The principal lesion in these cases is a hyperplasia of the dermal glands and connective tissue, and the removal of this hypertrophied tissue can be accomplished by simply shaving off the superabundant material with a razor. The finger may be held in the nostril and all irregular elevation trimmed away. In a case which the writer reports this was done under cocaine, and on the second day after operation bits of new epidermis could be detected which had proliferated from the remnants of the glands. The cosmetic result was excellent.

Belladonna Poisoning in Ophthalmic Practice. J. Fefler calls attention to the risks attending the administration of belladonna and that special care must be given to the mode

of administration and the dosage. In one case which he reports, toxic symptoms followed the taking of a powder in which belladonna was one of the ingredients. In this instance it was found that the powder was not thoroughly mixed and the belladonna was unequally distributed, showing the necessity for prescribing in divided doses instead of in bulk. Paralysis of the ocular muscles came on, however, before any other symptoms were noted. In another case temporary blindness, lasting five days, followed the administration of a similar powder, the daily dose averaging about 0.09 gm.

Münchener medizinsche Wochenschrift, August, 9, 1904.

Pressure in the Auricles in the Presence of Valvular Defects.—A. Horner has made a series of measurements in both healthy and ill persons which are based on the suggestions of Frey and Gärtner, that the pressure in the right auricle may be gauged by the height to which it is necessary to raise the arm in order to empty the veins. Observation in a number of cases of mitral insufficiency and stenosis showed that the auricular pressure in most instances did not exceed that of the normal heart, or only to a very slight degree. For this reason it would not be wise to exclude cardiac disease, even where the veins are emptied at a normal height.

Cardiac Disturbances in Scarlatina and Their Consequences.—Schmaltz states that less attention is given to the cardiac complications of scarlet fever than to those of diphtheria, because the severe conditions met with in the latter case are seldom attendant upon the former. The writer, in a material comprising 191 cases, has observed, however, that abnormal circulatory conditions were present in 35 per cent. These were accompanied in most instances by comparatively slight subjective symptoms—mostly palpitation and dyspnœa of a moderate degree. It was noted, moreover, that these symptoms depended in no manner on the severity of the original disease, the milder cases seemed to be the most often afflicted. Comparative observations disclosed the fact that cardiac complications following scarlatina lead to permanent disturbances more frequently than those attendant upon diphtheria. Of the cases reported, thirteen came to autopsy, and in only one of these could any disease of the endocardium on the valves be demonstrated. In another series of thirty-three cases, recent valvular changes were noted in only three instances. There is no doubt, therefore, that the clinical signs which are observed during the period of convalescence in scarlatina, are in the large majority of cases due to a myocarditis rather than to an endocarditis. The latter fact has been confirmed by Romberg on microscopical examination. The writer desires to call attention to the necessity of watching scarlet-fever patients carefully during the stage of convalescence, and the best therapeutic measure, in his estimation, is continued rest with the addition of an ice-bag over the cardiac region when the heart action becomes tumultuous. From the use of digitalis he had little results.

French and Italian Journals.

Experimental Tuberculosis of the Salivary Glands.—P. L. Fiorani has made experiments on dogs as to the possibility of infecting the salivary glands with human tuberculosis. The infection might occur by way of the lymphatics, the blood or the excretory ducts of the gland. There are two forms of salivary tuberculosis, a diffuse and a confluent infection; the latter is the most frequent. The author concludes as follows: (1) The normal salivary gland, even when the duct has been obliterated, is with difficulty attacked by the tubercle bacillus. (2) When the conditions are altered from the normal by traumatism, the gland is easily attacked. (3) When the conditions are thus altered, it is easy to produce the infection by inoculating the germs by way of the excretory duct. (4) This form of infection gives localized deposits in the glands. (5) It is always circumscribed. (6) Macroscopically and microscopically it corresponds to the lesion found in man.—*La Riforma Medica*, July 27, 1904.

Generalized Peritonitis of Appendicular Origin.—L. Bérard declares that in the majority of cases of acute appendicitis medical treatment should be instituted before any other. The numerous successes due to it are not contested by the modern physician or surgeon. Nevertheless, there are certain forms or rather certain phases of acute appendicits in which surgical intervention is necessary. Too often patients are first seen when the peritoneum is already widely infected. Operation offers the only hope. This chance is slight, it is true, but should be offered to the patient, regardless of statistics. In every case of appendicitis, however slight, which has been followed from the beginning, and has been rationally treated by means of ice, suitable diet and repose, if on the second or third day, the symptoms, both local and general, have not clearly subsided, the case ought to be referred to a surgeon for his opinion as to operation. For although useless operations have been performed, nevertheless, cases may often be saved by surgical intervention which otherwise would be left to die with peritonitis.—*Le Bulletin Médical*, August 3, 1904.

Papillomatous Tumor of the Larynx in a Man of Sixty Years; Operation, Recurrence, and Death.—Duret and Lavrand report this case. The patient first complained of trouble in swallowing. Operation was advised on account of the fact that the patient could not obtain sufficient nourishment on account of the pain in swallowing. The tumor, also, appeared to be clearly limited to the larynx without any extra laryngeal invasion. The tumor, therefore, was removed. It was pediculated. Its surface was very irregular and papillomatous at certain points. In other places, it was slightly ulcerated. Even with the naked eye, the epitheliomatous character of the mass could be discerned, in spite of the benign appearance of the tumor at first sight. Microscopical examination showed stratified pavement epithelium. In the section near the pedicle, were seen vessels filled with blood, though as a whole, the tumor was only slightly vascular. The patient recovered, but some weeks later, a laryngoscopical examination showed a recurrence, although absolutely no symptoms, either local or functional had yet appeared. The general condition was excellent. Ulceration of the growth advanced, and the patient finally died. There had never been any dyspnœa in the history of the case.—*Journal des Siences Médicales de Lille*, July 30, 1904.

The Toxic Effect of Intestinal Worms.—L. Jammes and H. Mandoul have studied this question, about which there has been so much controversy, and have come to the following conclusions concerning it: The exceptional production of disorders in the hosts of common intestinal worms, and the innocuous liquids extracted from the bodies of these worms, tend to demonstrate that the morbid manifestations observed in the hosts, cannot be related to the habitually toxic properties of the secretions of the worms. It seems more rational to believe that the disorders produced by these worms, are due essentially to mechanical causes. These are sufficient to explain the phenomena which have been observed. The irritation caused by the action of the worms on the intestinal mucosa, is the starting point of various disorders: the symptomatology of these disorders does not differ at all from that of ordinary digestive troubles. These disorders will vary with the conditions present, such as the number, seat, mode of nutrition and so on, of the parasite, as well as with the degree of sensitiveness of the host. To these purely mechanical effects, there may be added, in relation to the ascaris, the action of the volatile substance, the irritating effect of which, on the mucous membranes of various parts of the body, has often been noted. This substance may also have some effect on the intestinal mucosa, but even if this is true, it is hardly worth mentioning. Intestinal worms ought not to be considered as the absolute cause of troubles which are sometimes coincident with their presence, but as agents acting indirectly in certain conditions as the occasional cause of various morbid manifestations.—*Le Bulletin Médical*, July 6, 1904.

Non-tuberculous Meningitis, of Prolonged Duration, Cured by Lumbar Puncture.—M. Moukhtar reviews the history of a boy of fifteen years, who was admitted to the medical clinic of Bard with symptoms of meningitis. Lumbar puncture revealed polynuclears only. On the third day there developed in the patient, quite suddenly, a right hemiplegia with complete motor aphasia. The aphasia commenced to disappear three days later, and six days after its appearance the patient spoke as he formerly did. As to the paralysis, improvement was very marked during the first five days, but the patient was decidedly weak on his right side throughout his entire illness. Babinski's sign was very clear. On the eighth and fourteenth days, lumbar puncture was again practised, and the polymorphonuclears were seen both times in great abundance. Cultures remained sterile. Since that time there have been periods of remission and exacerbation. The remissions lasted from three to five days, during which time the patient felt very well, in spite of the persistent fever. Again, the phenomena of meningitis would reappear without any apparent cause, the pulse would become irregular, and the patient would sometimes fall into a state of profound coma. It was at this time that lumbar puncture was practised, and it was repeated twelve times. The effect was very favorable. The patient appears to be cured. There remains only a slight weakness of the right hand and leg. Bard calls attention to the value of lumbar puncture in relation to the diagnosis and treatment of these affections, for in the present case the symptoms were as characteristic of tuberculous meningitis as of septic meningitis, but the results of lumbar puncture have pointed to the presence of septic meningitis.—*Le Bulletin Médical*, July 30, 1904.

Book Reviews.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital; one-time Clinical Professor of Diseases of Children in the University of Pennsylvania; Member of the Association of American Physicians, etc. Assisted by H. R. M. Landis, M.D., Assistant Physician to the Medical Dispensary of the Jefferson Medical College Hospital; Member of the Staff of the Henry Phipps Institute for the Study, Treatment, and Prevention of Tuberculosis. March 1, 1904. Surgery of the Head, Neck, and Thorax—Infectious Diseases, Including Acute Rheumatism, Croupous Pneumonia, and Influenza—The Disease of Children—Laryngology and Rhinology—Otology. Philadelphia: Lea Brothers & Co., 1904.

The publishers claim for this quarterly that it now equals as a conspectus of medical progress the German Jahrbücher. In some features it might be said that the claim is too modest. American works of the kind have at times the advantage of working practicability. Too much space is not devoted to pure strict science to make the work prosy to the practical worker seeking aid. The serial under consideration has established a reputation on its careful selection of sub or department editors who appreciated the needs of the American subscriber. Condensation, cutting out of all burdensome matter in scientific and clinical reports, and giving what appears to the department head the essentials for the largest number of readers has been the evident aim. The present issue has the usual chapters reviewing the progress for the quarter in the different branches with comments of the editors. As a useful and accurate review we can recommend it.

Diseases of the Intestines and Peritoneum. By Prof. D. H. Nothnagel. Edited with Additions by H. D. Rolleston, M.D., F.R.C.P. Translated by A. Stengel, M.D. Philadelphia, New York, and London: W. B. Saunders & Co., 1904.

The author of this work having such world-wide fame, especially in this field of medicine, his book hardly requires any commendation. The reader will find it full of useful information.

Nothnagel does not think much of the value of intestinal antiseptics. None of the so-called intestinal antiseptics, he says, really deserves that name. There is only one means of securing anything like intestinal antisepsis, and that is a thorough emptying of the bowels. To this end calomel ranks first in effectiveness. Not only is it a powerful purgative, but it has the additional advantage that all, or nearly all, bacteria removed with the calomel stools are completely destroyed within twenty-four hours. Change of diet is another valuable means of modifying the intestinal flow and the chemical processes in the bowels as well.

Nothnagel recommends the use of opium in appendicitis. By forbidding opium, both the patient and the medical attendant are deprived of the best means of combating the disease. The chief objection, viz., that the drug masks the symptoms, is unimportant, he thinks, in comparison with its actual value, particularly if the case is carefully watched.

Tuberculosis and Acute General Miliary Tuberculosis. By Dr. G. Cornet of Berlin. Edited with additions, by Walter B. James, M.D., Professor of the Practice of Medicine in the College of Physicians and Surgeons (Columbia University), New York. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

It is a pleasure to peruse a volume so satisfactory and so well balanced as the one before us. The author has been ably seconded by the editor, who without interfering with the original text has brought it fully up to date (the volume is one of the series of Nothnagel's "Practice," issued several years ago) and has added much that is of value to American readers. Among these additions are sections on the relation of bovine to human tuberculosis, artificial immunity, the chemistry of the tubercle bacillus, and a list of sanatoria in the United States and Canada.

The first portion of the book treats of the etiology, the tubercle bacillus, its histology, its mode of invasion, the factors in infection, and the significance of heredity and predisposition. The second part gives the lesions, symptoms, course, diagnosis, and complications, together with the prophylaxis and treatment. Over a hundred pages are allotted to the concluding section, dealing with acute miliary tuberculosis.

The work is not simply a compilation, but represents the weighed knowledge of an expert who has thoroughly considered his material, discarding much that is currently accepted and pointing out errors in the usual statistics.

The translation is excellent and runs very smoothly, making the subject-matter easily understood and grasped with a minimum of effort.

A Manual of Fever Nursing By Reynold Webb Wilcox, M.A., M.D., LL.D., Professor of Medicine in the New York Post-Graduate Medical School and Hospital; Consulting Physician to the Nassau Hospital; Visiting Physician to St. Mark's Hospital; Fellow of the American Academy of Medicine; Member of the American Therapeutic Society, etc. Illustrated. 236 pages. Philadelphia: P. Blakiston's Son & Co., 1904.

This little volume consists of a series of lectures delivered originally to the nurses at St. Mark's Hospital. The author employs simple language throughout, thus making the work adapted to less advanced students and nurses as well as to practitioners. The first portion of the book treats of fever in general, its causes, varieties, symptoms, and treatment; embracing also diet lists, beverages, quarantine, and disinfection. Full details are given regarding the preparation of the sick room, and many hints for the comfort of the patient are added.

The second half of the work takes up the fevers as special diseases, describes their usual symptoms and the complications of each, and a graphic temperature chart is given to let the attendant know the normal course, an unusual deviation from which might necessitate a report from nurse to doctor.

The advice given accords in general with the usual treatment of to-day and can be considered trustworthy and reliable.

Diseases of the Intestines. By Dr. I. Boas; Specialist for Gastrointestinal Diseases in Berlin. Second Revised and Enlarged American Edition. Translated by Permission from the German Edition with Special Notations and Additions. By Seymour Basch, M.D., New York City. With forty-eight illustrations. New York and London: D. Appleton & Company, 1904.

The second edition appearing so soon after the first speaks well for the popularity and need of works of this kind. Although the text follows very closely that of its predecessor, we note a few additions which bring the work up to date and make it more complete. By far the most important of these is the new chapter on dysentery, in which the author takes up the most recent investigations regarding the etiology of the various forms and gives statistics which have a bearing on the results of the newer methods of treatment. The other two additions consist in a chapter on actinomycosis and on syphilis of the intestines, which are interesting, although the affections are of unusual occurrence.

The work can be recommended as an exposition of the views of one who speaks from personal experience and whose clinical observations have been extensive.

A Textbook of Mechanotherapy. (Massage and Medical Gymnastics.) Prepared for the Use of Medical Students, Trained Nurses, and Medical Gymnasts. By Axel V. Grafstrom, B.Sc., M.D., Late Lieutenant in the Royal Swedish Army; Late House Physician City Hospital, New York; Attending Physician to the Gustavus Adolphus Orphanage, Jamestown, N. Y. Second Edition. Revised and Enlarged. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

The present edition has been rewritten entirely as well as being very much enlarged. There are two new chapters—one on Massage of the Eye, Ear, Nose, and Throat, and the other on Pelvic Massage. The book is intended for students, trained nurses, and medical gymnasts, and as a reference book for the general practitioner. It well fulfils its purpose.

Practical Materia Medica for Nurses, with an Appendix Containing Poisons and Their Antidotes, with Poison Emergencies, Mineral Waters, Weights and Measures, Dose List, and a Glossary of the Terms Used in Materia Medica and Therapeutics. By Emily A. M. Stoney, Graduate of the Training School for Nurses, Lawrence, Mass.; late Head Nurse, Mercy Hospital Chicago, Ill.; late Superintendent of Training School for Nurses, Carney Hospital, South Boston, Mass.; Author of "Practical Points in Nursing." Second Edition. Thoroughly Revised. Philadelphia, New York, and London: W. B. Saunders & Company, 1904.

This well-known work now appears in its second edition. The entire text has been very carefully revised, and may be depended upon for accuracy. The style is clear and definite. New drugs, which have been proved to be of real therapeutic value, are considered with their preparations, uses, and doses. There is much valuable matter to be found in the appendix, such as Poison Emergencies, Dose Lists, Weights and Measures, etc., as well as a glossary of the terms used in materia medica. The first edition has proved of great value to the nursing profession, and the present volume will undoubtedly be even more useful.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Sixteenth Annual Meeting at Detroit, Michigan, May 30 and 31 and June 1.

AUGUSTUS CAILLÉ, M.D., PRESIDENT, IN THE CHAIR.
(Special Report to the MEDICAL RECORD).

Monday, May 30—First Day.

Intussusception; Cure by Sloughing of the Intussusceptum.—Dr. IRVING M. SNOW of Buffalo reported this case, occurring in a baby, seven months old, with illness of sixteen days, with symptoms simulating ileocolitis on the sixteenth day and protrusion of a gangrenous intestine from the anus. The removal of six inches of necrotic intestine hanging outside the sphincter was followed by recovery. Dr. Snow also gave the abstract of four similar cases.

Influence of Laboratory Feeding on Infants with Diseases of the Gastroenteric Tract, with Special Reference to the Weight Index.—Dr. MAYNARD LADD of Boston presented this communication. The influence of laboratory feeding was studied in 216 infants with diseases of the gastrointestinal tract, the great majority of which were cases of fermental diarrhœa and ileocolitis. The acute cases were ill on the average of seventeen days and the chronic cases 3.2 months before they were brought to the clinic for treatment. They were treated for lengths of time varying from one to thirty-one weeks. As an aid in comparing the influence of the feeding upon infants of different ages and stages of development, the nutrition of each infant at the beginning and the end of treatment was judged by the estimation of its weight development. This was calculated from the *weight index*, which was simply the ratio of the weight of a given infant to the weight of the average normal infant of the same age. Judged by this standard, over 50 per cent. of the cases had a weight development of only 40 to 70 per cent. when first seen. In giving results of the treatment, the series was divided into four groups:

1. Infants which maintained or increased their weight index while on laboratory milk and entirely recovered from the acute gastric and intestinal symptoms for which they were brought to the clinic. This group comprised 109 cases, or 50.4 per cent. The group as a whole gained 8 per cent. in weight index, or a maximum average gain per week of 156 grams from the lowest weight reached during treatment.

2. Infants which showed a loss in weight indices and yet recovered from the acute gastric and intestinal symptoms and showed material gains in weight. This group includes fifty-eight cases, or 26.8 per cent. The maximum gain per week from the lowest weight reached was 94 grams. This was not sufficient to maintain the weight indices the average loss of which was 3.4 per cent. This group received treatment on the average for only 5.9 weeks as compared with 8.5 weeks in group 1.

3. Infants which, for the most part, recovered from the acute gastric and intestinal symptoms while under treatment but whose weight was not materially increased. This group includes thirty-seven cases, or 17.2 per cent. The average length of treatment was 3.7 weeks, the loss in weight index 7.2 per cent. and the average loss in weight from the lowest point reached was 6.5 grams per week. Eleven cases in this group were "not improved" while under treatment. Of these eight could not be traced and some of them might have died.

4. The fatal cases. These were twelve in number, making a mortality of 5.6 per cent. in the series of 216 cases, the results of which were known at the time the treatment was stopped.

Disturbances from High Fat Percentage in Infant Feeding.—Dr. L. E. HOLT of New York said that he was convinced that many physicians and nurses greatly erred in respect to the fat in feeding by the percentage meth d, with at times most serious results. This was particularly so when they selected a very rich or Jersey milk with 5 per cent. or 5.5 per cent. fat, because the average milk looked so blue and poor; they used this as they would have employed an ordinary 4 per cent. fat milk. Therefore, instead of giving in the formula a 3.5 or 4 per cent. fat, as they intended, the fat had often been 5 per cent., 6 per cent., or even higher. The object of the paper was to record some of the results seen when such high fats had been added. In the first cases reported the following points were noted: The suddenness and severity of the disturbances; the convulsions, tetany, and laryngismus stridulus; the very large liver; the stools consisting of almost pure fat; the cessation of the nervous symptoms on reduction of the fat and their return one week later, the fat meanwhile having been put back to nearly previous strength. The points that were noted in the second case were as follows: Development of slight rickets, as shown by late dentition and craniotabes; the return of convulsions one week after the first ones occurred, the fat meanwhile having been increased to nearly full strength; the bowels were constipated unless magnesia was given. With increasing experience Dr. Holt said he was using less fat and higher proteids, especially in those cases in which there was much derangement of digestion.

Dr. CHARLES G. KERLEY of New York said that he could not get the same results as Dr. Ladd, and he gave a smaller amount until the fever was normal and the activity of the bowels had ceased and the stools were practically normal, then he gave a weak formula and never over ½ per cent. fat and 4 or 5 sugar. In the Infant's Asylum in New York he said they were unable to get milk containing more than 2 per cent. fat to children under six months of age; these children were less susceptible to intestinal derangements, they thrived better in every respect on a low fat milk.

Dr. ROWLAND G. FREEMAN of New York said the most important thing in the paper was the working out of the weight index, and he asked if it would not be better to substitute for the weight index measurements of the length; if a child weighed five pounds at birth and measured seventeen inches in length he thought the weight index should be corrected for that child. Regarding high fats, he said that much ignorance existed as to what was high fats and what was cream; in the books cream was ordered; and mothers or nurses added cream to the milk regardless of the fact that it might be a centrifugal cream of 40 per cent. instead of the usual 16 per cent. fat.

Dr. FLOYD M. CRANDALL of New York thought that the general practitioner should have in mind what Dr. Holt said regarding constipation and the ingestion of fats; it was a very important point.

Dr. J. LOVETT MORSE of Boston corroborated all that had been said regarding high fat. Eczema was often due to too high fat. Another sign he had not heard mentioned was the ammoniacal urine, which would cease when the fats were reduced.

Dr. THOMAS M. ROTCH of Boston believed that the study of fats should be more extensively carried out than it had been; the intelligent use of fats was to be advocated. Some babies had constipation and some had diarrhœa as the result of high fat. A baby may have a perfect fat digestion and yet become weaker and develop serious nervous symptoms.

Dr. B. K. RACHFORD of Cincinnati asked what was the cause of the nervous conditions which developed from too high fat feeding; was it an autointoxication?

Dr. L. E. La FETRA of New York said that in his experience babies born prematurely, weighing 4, 5, or 6 pounds, would increase in weight more rapidly than others, and at the end of one year would weigh three times the birth weight.

Dr. J. E. Winters of New York said that these disturbances referred to were not due to percentages but to too frequent feedings. Constipation was not due to the high fat so much as to the excess of food beyond what any child should take.

Dr. A. Jacobi of New York said that he had been writing and speaking on this subject for forty or fifty years and yet he was not prepared to enlighten them regarding it. In nearly all these cases indican would be found and that denoted intoxication. It had been stated that little babies would tolerate fat and the older ones would not, but that was not so because little babies would not tolerate fat at all. With regard to the constipation, the cause lay in the insufficiency of the muscular layers. These babies were fat, rotund, and weighed much, but it was only fat and no muscle. Regarding the amount of fat, he believed that they would thrive on milk with a little over 2 per cent. fat.

Dr. Ladd, in answer to Dr. Freeman, said that he had not taken any measurements at all, his paper referring to weights and not to lengths.

Dr. Holt said there were two kinds of cases, one in which the milk must be stopped at once for a short time, the other in which it must be stopped for a long time. He thought it was a mistake in the summer diarrhœas of children to keep them too long from milk. In the first class of cases, in which there might be an acute intoxication, they must be kept off the milk until they are almost well. This was a different class of cases from those in which there was simply an intestinal indigestion due to dysenteric organisms.

Congenital Hypertrophic Stenosis of the Pylorus in an Infant.—Dr. John Dorning of New York read this paper. The child was born March 23, 1903, after a natural labor, of healthy parents. Weighed at birth 8½ pounds. The diet was breast milk exclusively. Child vomited after nursing. The mother never noticed mucus in the vomit and the milk was always returned fluid. The baby seemed to be able to retain water; it would frequently sleep twelve hours, and never awoke more than once during the night, and seemed always to be sleepy. The bowels moved several times a day, always yellow in color and digested. The baby grew long, the face was plump and body not thin, but the arms and legs were always very emaciated. The above history was obtained from the mother. On May 24 Dr. Dorning saw the baby, and he found a pale, extremely emaciated, very weak, and listless infant. The abdomen was somewhat distended, but soft, tympanitic, and not tender on pressure. A small mass could be found in the epigastric region, just to the right of the median line. On June 7 the baby became unconscious while nursing and died two hours later. Autopsy was performed on June 8. The stomach was distended, the pylorus thickened and hard, and the duodenum one inch beyond the pylorus was deeply congested. The gastric mucous membrane was pale and showed no ulceration. The wall of the stomach presented a decided thickening toward the pylorus. Dr. Dorning said there were now on record about sixty cases of this condition. A study of the literature led one to infer that there were either two distinct pathological conditions with similar clinical manifestations, one amenable to dietetic management, the other fatal, unless relieved by operation, or that there were simply varying grades of one and the same lesion. The diagnostic symptoms of hypertrophic stenosis of the pylorus are persistent and apparently causeless vomiting, progressive wasting, and a palpable pylorus. The absence of bile in the vomitus would ordinarily indicate an obstruction to be above the entrance of the common bile duct; its presence, however, would not exclude pyloric stenosis. In cases of moderate stenosis, in which muscular spasm is, perhaps, a prominent factor, the gastric symptoms, though sometimes rather pronounced, are generally not very urgent in character, and improve and even seem to subside under dietetic treatment. The presence of a palpable tumor in the region of the pylorus in conjunction with the previously mentioned symptoms, established the diagnosis beyond a reasonable doubt. As it was not always possible to detect, with palpating fingers, small masses in the upper abdominal zone, its absence did not altogether negative the diagnosis. When the patient's condition would warrant it, an examination under anæsthesia might disclose the presence of a thickened pylorus, not otherwise to be detected. The symptoms of congenital pyloric stenosis were practically those of pyloric obstruction, and other lesions were so rare in infancy that when symptoms of pyloric obstruction were in evidence this condition should at least be strongly suspected. Every case was not necessarily immediately fatal. Some children lived to a more or less advanced age, suffering all the time more or less marked dyspeptic symptoms.

A Cure of Chronic Nephritis Following Renal Decapsulation.—Dr. Augustus Caillé of New York reported the case of a girl, four and a half years old, suffering from chronic nephritis. The urine was scanty and dark, containing albumin, casts, renal elements, blood, and pus. The eyes were puffy and the abdomen contained fluid. After a course of sweating, intestinal irrigation, diuretics, and diaphoretics, she returned home improved, but nine months later again was an inmate of the hospital. There was general œdema, with enlarged heart, the apex beat being at the sixth interspace, an inch to the left of the nipple line. A decapsulation of both kidneys was performed, and there was found a typical chronic parenchymatous nephritis, the large white kidney, on both sides. Each kidney measured over four inches in length and was three times larger in bulk than normal. There was primary union of both wounds and convalescence was uneventful. After the discharge from the hospital there was no more œdema, no headache, and no uræmia. The patient for a year past had been in perfect health and had taken up her school life. The urine was practically normal and the general health was all that could be desired.

Dr. Caillé said that, from his observation in this case and in other cases that had come under his observation, he would not hesitate to advise inspection of the kidneys through lumbar incision in cases in which an acute nephritis, not secondary to cardiac lesions, did not clear up in a reasonable time, say six or eight months; and he would furthermore advise splitting the capsule or decapsulating one or both organs, should they appear swollen and enlarged, with the hope of preventing an acute nephritis from becoming chronic and incurable. The same procedure was indicated in cases of acute nephritis with complete suppression of urine.

Dr. Kerley of New York asked what the effects would be upon these children if they became victims of scarlet fever or other infectious diseases.

Dr. Caillé said he could not answer this question. The whole matter was new and very little positive definite knowledge on the subject was yet to be had. There were quite a number of cases that had been operated upon in a quiet way and not yet reported because the operators were waiting for results. In the case he reported he was convinced that the benefit from the operation was a very marked one, but whether it was due to increased blood supply or to massage incident to the handling of the organ or not he could not say. He said that Dr. Edebohls was preparing statistics showing, out of eighty cases operated upon, ten or twelve absolutely positive ideal cures, and eight or ten other practical cures. Dr. Caillé had seen the operation performed about twenty times without a mishap. He had seen better results from operation than he had from medication in these cases.

Some Observations on Epidemic Vulvovaginitis in Infants and Children.—Dr. A. C. Cotton of Chicago

presented this report of an epidemic of gonococcus infection which occurred in the hospital from August, 1902, to September, 1903, during which period 319 children were admitted. The first case was observed on August 8 in a boy, two years old, who had a urethral discharge. Gonococci was next found in the vulvovaginal discharge in a girl with typhoid fever. These two patients seemed to have given rise to the epidemic. Dr. Cotton formulated the following conclusions: Every hospital for children must be protected against infection from without by well-arranged detention wards, in which the newly admitted patient may be submitted to the closest scrutiny for a period of at least fourteen days to determine his freedom from acute infectious disease before admission to the general ward. A complete hospital should have ready for use properly located isolation wards to which patients may be removed upon the first appearance of suspicious symptoms of an acute infection. Gonorrhœa was a most formidable disease in a children's hospital, and female infants were peculiarly susceptible to this disease. A patient in a children's hospital showing gonorrhœa should be properly isolated and placed in charge of a special nurse. The interne or nurse while treating a gonorrhœa patient should be relieved from other duties in the wards. The efficiency of any isolation may be questioned which did not individualize strictly not only in regard to the treatment, care, and manipulation of the patient but also as to the use of clothing, bed linen, feeding untensils, thermometers, douche-pans, etc. The same care in sterilization by nurse and physician was necessary as would be observed in the case of any other acute infection.

Dr. A. Jacobi of New York said that undiapered children of two, three, or four years of age carry their fingers everywhere, and by preference about the abdomen, and it would be expected that they would carry pus to the eyelids, but such was not, as a rule, the case. No doubt all physicians had seen in these cases secondary involvement of the cervix, the uterus, occasionally nephritis, a pericarditis, etc., but a more favorable course was run in children than in adults.

Dr. Charles G. Kerley of New York said that at the Babies Hospital there were fifteen or twenty cases of genococcal arthritis in two years, and it was peculiar that there was found no evident source of infection. Dr. Kimball had reported eight cases, seven in boys, and the only possible source of infection was a stomatitis. In the boy there were no local lesions.

Dr. Jacobi had seen one case in which there was a myositis.

Dr. L. E. La Fetra said he had seen two cases of gonorrhœal arthritis, one in a baby three weeks old, the other in a child eight months old. In the case of the baby the source of the infection appeared to come from the mother; the child had been circumcised and the mother had gonorrhœa at the time the baby was born.

Dr. Isaac Abt of Chicago had seen but two cases of vulvovaginitis with complications, one being an arthritis the other a cystitis.

Dr. Augustus Caillé of New York said that some years ago the attention of the Post-Graduate Hospital was called to this disease by reason of a suit against the institution. A child was admitted apparently in good health; ten days later she developed a severe specific vulvovaginitis. Every child now admitted to the institution was carefully examined and a swab culture made. If gonococci were found the child was rejected.

Dr. Samuel S. Adams of Washington, D. C., referred to a family of seven children, all of whom were infected from both father and mother; they were admitted to the hospital and successfully treated in a short time. Each of these children had alternately slept in the bed with their parents and so contracted their vulvovaginitis.

A Case of Carbolic Acid Poisoning Simulating Acute Scarlatinal Nephritis.—Dr. Samuel S. Adams of Washington, D. C., reported this case. The patient was a child of ten years, white, who had a moderately severe attack of scarlet fever without any troublesome symptoms, and who was first seen by him February 3, 1904. On the 9th the child complained of intense itching, and he instructed the mother to bath her twice daily with a solution of commercial carbolic acid and water, a teaspoonful to the quart. On the 19th she was again visited and found to be in excellent condition. Desquamation was very profuse. The itching had been allayed by the baths, and there was apparently no tingling or irritation from the carbolic acid. On February 22 the report was received that the child was bright and happy, but had passed some dark urine, a specimen of which was sent him. Examination of this showed albumin, red cells, and hyaline and granular casts, all in moderate numbers. When he saw the patient the eyes were puffy; otherwise she was in good condition. The baths were stopped. On the 24th the puffiness had disappeared. The urine gradually improved. Dr. Adams said that, having previously reported cases of carbolic poisoning following its use on the skin, he was satisfied from the uranalysis made that the nephritic symptoms were due to the irritation of the drug and not to the toxæmic effects of the scarlatina. This opinion was confirmed by the speedy relief of the kidney irritation *pari pasu* with the elimination of the carbolic acid. Such a weak solution of the acid was used, it seemed to him reasonable, to attribute the toxic effect to an idiosyncrasy on the part of the patient.

Gastrointestinal Toxæmia.—Dr. B. K. Rachford of Cincinnati read this paper. He said that gastrointestinal toxæmia, as differentiated from autointoxication, was a systemic intoxication, produced by poisons formed in and absorbed from the gastrointestinal canal. He said it was possible that the poisons produced by bacteria in the intestinal canal might have their origin from three different sources: (1) The components of dead bacteria might furnish a certain amount of proteins as, for example, tuberculin, which is a portion of the tubercle bacillus. (2) Living bacteria in the intestinal canal might and did excrete ferments or toxins, capable of producing the most profound symptoms. (3) Substances produced by bacteria from the culture media were possibly important sources of intestinal intoxication. Among the poisons of this class ptomains held the most important place. Acute intestinal toxæmia, he said, was more common in the infant and young child than in the adult, and was probably due chiefly to the great irritability and the immaturity of the child's nervous system. A small quantity of the poison absorbed might produce high fever, convulsions, and other pronounced nervous symptoms which in an adult might be easily resisted. It was also true that severe albuminous fermentations, capable of producing virulent toxins, were more common in the child than in the adult. This was probably due to the fact that the hydrochloric acid function of the stomach was not so well developed in the young child as in the adult, and therefore not capable of exercising the some control in preventing intestinal fermentation.

It was to chronic intestinal toxæmia that he wished to call special attention, because of its importance as an etiological factor in producing nervous symptoms in children, and which was so often overlooked. This form might be associated with diarrhœa, although constipation might exist. In order to prevent hyperfermentation and increased absorption of intestinal toxins the food material should not be allowed to be retarded, and when ejected the fæces should have the moist form of a normal intestinal evacuation. So important was the rôle played by chronic intestinal toxæmia in the production of neurotic

diseases in a child that he invariably began his treatment of nervous diseases by a careful investigation of the intestinal canal. Among the symptoms which might be produced or exaggerated by intestinal toxæmia might be mentioned malnutrition, anæmia, headaches, general malaise, fever, heightened reflexes, general nervous irritability, hysterical and neurasthenic symptoms, bradycardia, hyperæsthesia, nervous anxiety, psychoses, etc. The urine furnished valuable evidence of the existence of intestinal intoxication by showing the presence of indican and the ethereal sulphates. The etiological importance of the vegetable organisms in producing intestinal toxæmia should not cause one to overlook the rôle animal parasites play.

Dr. A. Jacobi of New York said that formerly the textbooks gave worms as a cause of the symptoms as described. The raw vegetables, such as are taken in Germany and Hungary, would produce just such a train of symptoms. Dr. Jacobi had frequently thought that a protracted anæmia would cause an insufficient secretion of gastric and pancreatic juices and so interfere with normal digestion. The presence of indican in the urine added much to the ease in diagnosis.

Dr. F. Forchheimer of Cincinnati said that he had been interested in this subject for years, especially as many men did not believe in the existence of this condition as an etiological factor. When indican became so much talked about the speaker examined the urine in all cases in which a diagnosis of chronic intestinal autointoxication was made, and in a very large number of cases indican was not present at all. To find indican in the urine once meant nothing at all; but if found many times after repeated examinations then it was to be presumed that there was some abnormal condition going on in the intestinal canal. In children there was an accumulation of fecal material in peculiar shaped places, *i.e.* in the intestines where there were extra curvatures, as at the sigmoid, the fæces being retained for some time, and this accounted for the constipation and also for the diarrhœa; for when fecal matter remained in one place a certain length of time diarrhœa followed. But in adults the condition was different. Here the special places for the deposit of fecal matter were at various curvatures, at the sigmoid flexure, at the hepatic flexure, at the splenic flexure, and at the head of the colon. Sometimes the whole of the large intestine was blocked up. He wished to lay particular stress upon the condition he had once described as chronic ulcerative stomatitis, which occurred in children quite rarely and in adults quite frequently in the form of Riggs' disease. Curiously enough, in Riggs' disease he had always found uric acid, and he came to the conclusion that uric acid was due to some autointoxication.

Dr. B. K. Rachford of Cincinnati said there were cases of autointoxication in which indican did not occur in the urine because fermentation had not occurred. Again there was a class of cases in which indican could be found in the urine and without any clinical symptoms of autointoxication, possibly because the child was able to resist it and filter the poison and so manage it. Indol was formed in the intestinal canal by hyperfermentation and was one of the results of putrefaction; it was a poison and probably was associated with other poisons about which nothing was known. The presence of indican in the urine meant the presence of indol in the intestinal canal, therefore there was a relationship.

Clinical Manifestations of Acute Otitis in Children; a Study of Fifty-one Cases in Private Practice.—Dr. Charles G. Kerley of New York reported a few of these cases, illustrating them by a number of temperature charts.

(To Be Continued).

Infantile Syphilis.—Schwab and Levi-Bing advise the use of hypodermic injections of biniodide of mercury in doses of 1 to 2 milligrams in aqueous solution, given once daily.—*La Presse Médicale.*

BRITISH MEDICAL ASSOCIATION.

Seventy-second Annual Meeting, Held at Oxford, July 26, 27, 28, and 29, 1904.

(Special Report to the Medical Record.)

(Continued from page 355.)

SECTION OF TROPICAL DISEASES.

Second Day—Thursday, July 28.

The Prophylaxis of Malaria.—Dr. T. W. W. Stephens, Walter Meyers Lecturer in Tropical Medicine, Liverpool University, opened this discussion. He said it was not unnecessary even now to point out how malaria is contracted. Not one in a hundred laymen in the tropics knew that malaria was a contagious disease. The source of contagion unsuspected by the layman, lay in the fact that in the tropics the native population, especially the child population, carried malarial parasites in its blood, often while presenting not the least outward sign of sickness. It was now known that certain mosquitos of the sub-family Anophelina alone could convey the contagion. There exist about a hundred species of Anophelines, but of a dozen species only could we say with any certainty they conveyed malaria. In two very malarial places in India, Mian Mir (Punjab) and Ennur (Madras) there were caught in the same huts at the same time two species of Anophelines *M. rosii* and *M. culicifacies*. Actual dissection showed that *M. rossii* contained no parasites (sporozoits), and therefore was not carrying malaria under conditions in which *M. culicifacies* was. These observations had been repeated by others with the same result. *M. rosii* did not in nature convey malaria. This, while scientifically of great interest, was also of practical value. Should we spend money and occupy our time in eradicating *M. rossi* when, as far as we know, it is not concerned in the transmission of malaria? Recently Hirshberg, in the United States, obtained similar results, though in this case by feeding experiments. Two species, *Anopheles maculipennis* and *A. punctipennis* were fed on the same subject of malignant tertian malaria under the same conditions, with the following result: *A. maculipennis*, number fed, 48; number infected, 8; *A. punctipennis*, number fed, 58, number infected, 0.

Similar results have also been obtained in Japan. The practical bearing of these facts was obvious. If we could positively state that a certain species of Anophelia did not transmit malaria it would obviously simplify operations directed against mosquitos. Broadly speaking, each Anopheline has a breeding ground of its own. For instance, whereas *M. rossi* breeds in the shallow pool or puddle some inches deep only, *M. culicifacies* loves clear fresh water of streams, rivers, canals, and other moving waters. Now if it is true that *M. rossi* does not carry malaria it is unecessary to attack the breeding grounds of *M. rossi*.

Another important problem was that of flight of mosquitos. If mosquitos could really fly fifteen miles, as stated by some authors, whatever might be done to free a place from Anophelines, it would be impossible to prevent their return and undoing all one's labors. But close observations showed that under ordinary conditions nothing of the kind happened. The normal flight of Anophelines being a matter of some hundred yards, the prophylaxis of malaria would not be best achieved by blindly proceeding to act against mosquitos as a whole, but by careful action based upon accurate study of all the habits of mosquitos. Of the modes of prophylaxis the antilarval method appeared to be fundamental and thorough, provided it took the form of a systematic drainage. Its merits consisted in the obvious fact that as the mosquito breeds in water, if this water could be drained away the number of larvæ in that area must diminish, and if there was no influx from without, the number of mosquitos also. That by mechanical prophylaxis excellent results could be got, was shown in Italy. The Japanese had likewise applied it to their troops, with the remarkable result that

in a particular regiment the entries diminished from 2,000 odd in 1900 to 256 in the first six months of 1903. Prophylaxis by means of quinine was an excellent method. But its applicability was somewhat limited.

The segregation of Europeans was another definite prophylactic measure, based upon the fact that the natives are the source of European infection in the tropics. It has been said that this method was not a just method, for the native was neglected. The native must be treated as the white man—within limits this was true, but the limits altered the nature of the case—when the sanitary and general education of the native population had made any progress whatever, it would then perhaps be possible to begin to treat natives and Europeans alike, but until that happy day arrived it was not right to sacrifice European lives to such false and sentimental ideas.

Dr. Stephens closed his paper by referring to the antimalarial operations carried out at Ismailia and Mian Mir. At Ismailia the campaign was against mosquitos as a whole, and it was difficult to know what the effect on the Anophelines had been. Indeed we did not even know what Anopheline was carrying malaria at Ismailia. Yet we had the brilliant result of the diminution of the fever entries from an average of 2,000 to 200 roughly. As to Mian Mir, the selection of the locality was unfortunate. The preliminary survey was very thorough. All the species of Anophelines were collected. It was determined which were carrying malaria. The breeding places of each species were carefully mapped out. The endemic index of the various native bazaars was determined each month. Adequate care was taken to have control areas, the necessity of which was clearly shown during the operations, *e. g.* the endemic index in the area of operations at one time fell rapidly, and it might have been concluded that it was the result of the anti-larval measures, and indeed, one could not have said it was not, had it not been for the control. But in the control bazaar, where no measures were taken, a parallel fall in the endemic index took place. The Unfortunate factor that was not anticipated, viz., the flight of mosquitos into the area from as far as two miles away, had been discussed by Captain James and Lieutenant Christophers in their report on Mian Mir. Anyhow the Mian Mir experiment had taught some useful lessons. The difficulties were greater than were perhaps anticipated, but that they would be overcome there was no doubt. Prophylaxis, be it of typhoid fever, tuberculosis, or malaria, was necessarily slow in its progress. We should endeavor, however, to do our utmost to hasten it.

The Antimalarial Experiment at Mian Mir.—Major Ronald Ross, Professor of Tropical Medicine, University of Liverpool, criticised the Mian Mir experiment. He said he was not convinced that mosquito propagation at Mian Mir was really suppressed to the extent claimed. The test employed for detecting reduction in the number of mosquitos consisted of nothing but the formation of a personal impression, unsupported by definite figures. The figures given regarding variations in the amount of malaria were not sufficient to enable one to form any opinion one way or another. Several of the statements made in the reports appeared either to be contradictory or unintelligible, or to involve mathematical impossibilities. Even admitting the thoroughness of the work done and the validity of the tests used, the whole experiment was still open to the final criticism (*a*) that it might not have been continued long enough, and (*b*) that the radius of operation might not have been large enough. In conclusion, Major Ross thought that Lieutenant Christophers and Captain James were not entitled to claim any more than is contained in the following sentence, "That after operation extending to a half-mile radius and lasting a year and a half and costing between two and three hundred pounds, no very large reduction in the number of mosquitos or in the the amount of malaria was affected." James and Christophers apparently expected to banish all the mosquitos within their area of operation for a few hundred pounds. Malaria at Mian Mir must cost the Government alone some thousands of pounds annually. Logan Taylor spent over £1,000 for a preliminary draining of the waste puddles of Freetown. Ismailia, though it was both a smaller and an easier area to deal with than Mian Mir, cost £5,000 for the first year. According to Watson, Klang and Port Swettenham cost about £3,225 and £8,600 respectively for the first year's work. Sir William Mac Gregor had stated that Lagos has been costing about £10,000 per annum for antimalarial work. Work like that carried out at Mian Mir only tended to arrest enthusiasm in the cause without really adding anything definite to our knowledge.

The Success of Mosquito Destruction Operations.—Capt. S. C. James and Lieut. S. R. Christophers said that so many operations where mosquito destruction had been successfully carried out were reported that it appeared almost unnecessary to ask how far such measures might be considered of practical utility in diminishing the incidence of malaria. It was indeed only when one made a closer study of the reports of operations that it was realized in how many cases little or no proof of success was given and in how many the conclusion of success was based on such inconclusive evidence as the number of admissions to hospital and popular report. In perusing such accounts the author found it very difficult to reconcile the easy and triumphant successes with the extreme difficulty encountered in their efforts. The operation undertaken by the Government of India at Mian Mir were throughout very thorough. Every effort was made to make the destruction of breeding places complete and the experiments were continued for over two years. Many hundreds of pools were drained and filled, and throughout the whole area systematic search for and destruction of breeding places were consistently carried out. Here, then, if mosquito destruction was so readily brought about, as would seem from so many accounts, they would have been able to show a very marked and decided reduction in the number of adult anopheles and in the prevalence of malaria. As a matter of fact the result in both cases was poor and totally out of proportion to the means employed. To what, they asked, was to be ascribed the absence of the usual successful issue? They did not feel justified in considering it due to want of thoroughness in the conduct of the operations nor to peculiar conditions in Mian Mir. There was indeed little doubt that the difference was entirely due to the great disparity in the value of the tests used in estimating the reality of results achieved. Perhaps the most valuable result of the Mian Mir operations was that they gave an insight into the difficulties which are almost certainly to be encountered in most really malarious places. The speakers had found it very difficult to keep up with the ever-changing situation of anopheles breeding places under different degrees of rainfall. They found that they had to deal with breeding places at considerable distances, and that quite local destruction was utterly futile. Moreover, they had to count upon what appeared to have been the main factor causing their want of success, an infiltration of adult anopheles from outside the area which could not be prevented by any means in their power.

They fully realized the inadvisability of damping enterprise by the suggestion of possible failure, but they thought little good could result from proclaiming a successful issue, the evidence for which would not bear criticism. Mosquito operation reports were very often extremely uncritical and even ridiculous, since they claimed an amount of success for which they had no evidence. They hoped their remarks might not be without some result in directing attention to the need of more rigid experiments and the desirability of further knowledge regarding details being amassed which should enable us eventually to form a special branch of sanitary science dealing with this important subject.

Dr. Louis D. Sambon, Lecturer to the London School

of Tropical Medicine, said that the question whether only some species of Anophelines are able to carry malaria was one of great importance. Dr. Stephens having premised that certain species did not carry malaria, asked whether it was reasonable to waste money and labor to destroy such species as *M. rossii* which, though extremely abundant in certain areas in India, did not appear to be concerned in the malarial endemicity of the areas. He was inclined to question Dr. Stephen's premise. We had abundant evidence to show that the same species of Anopheline in different districts and at different epochs might or might not be a carrier of the infection. *Anopheles maculipennis* was the principal carrier of malaria in Italy, yet there were districts such as Fucecchio in Tuscany which have no malaria though abounding in *A. maculipennis*. In the Cambridgeshire Fen malaria used to be very prevalent at one time, now it is practically extinct, but *A. maculipennis* is still very numerous. In Holland malaria had disappeared, but a few years ago it broke out again and now is steadily increasing. *A. maculipennis* is the species of Anopheline most prevalent in that country. He believed that the fostering of certain parasites by mosquito depended on the different feeding habits of these insects in different places and on the peculiar circumstances of their respective environments, but we needed numerous and careful experiments to elucidate this question. We should do our utmost to find out the reason why certain species, or better, in certain localities, the local variety of certain species were not able to carry malarial infection, because such knowledge would probably enable us to combat malaria in an easy, economical, and efficient manner. In several papers he suggested that hyperparasitism was possibly the cause, the hyperparasite or secondary parasite destroying the malarial parasite within the body of the mosquito just as the larva of one ichneuman-fly destroys that of another species within the body of its capillary host. In the case of malaria, as also in the case of certain Filarial infections, a *Nosema*, the so-called "Brown spore," probably acts as a useful hyperparasite. Hyperparasitism is of universal occurrence in Nature, and no doubt it has an important rôle in pathology Some species of Anophelines seemed very partial to certain kinds of breeding grounds, others appeared to be far more indifferent, but it would be a mistake to believe that the nature of the breeding ground was invariably a matter of choice. Feeding opportunities and natural enemies were potent factors in the determination of larva-stations. According to his experience, the chief characteristic of larva-stations was their remarkable shiftiness. They shifted with the rise and fall of the water-table and with the appearance and disappearance of certain plants and animals. It would therefore be unwise to limit antilarval operations in any way whatsoever. As to the distance to which mosquitos could fly, it was again a matter of locality and œcology. Moreover, in certain years, under favorable conditions, mosquitos, like other insects, might swarm and extend their excursions.

As to prophylaxis, he thought the use of wire or cotton netting an excellent means of individual protection in the hands of intelligent people, but of no practical value when left to native and ignorant populations. The segregation of Europeans was neither practicable nor efficacious. At best it could only be regarded as a temporary measure. The wide administration of quinine to the infected population appeared to be a most commendable means of prophylaxis when possible. The value of efficient drainage and intense cultivation was, of course, undisputed.

Col. Kennett Macleod remarked that Dr. Stephens had omitted to mention the food of larval mosquitos. The different species of anopheline-larvæ probably subsisted on different food. Additional information was required on this point. The flight of mosquitos was very important with regard to the conveyance of the plasmodium from one part of the country to another, but Dr. Stephens forgot the conveyance of mosquitos by ships, caravans, railways, etc. He regretted that no mention had been made of the value of belts of trees and of plants believed to be prejudicial to the life of mosquitos. Dr. Stephens suggested that anti-malarial operations should be directed against the malaria germ-carriers and not against all species of anophelines. In the successful experiment at Ismailia, we are told that the battle was indiscriminate. In Havana also all mosquitos were dealt with, and Colonel Gorgas stated that the campaign did not only stamp out yellow fever, but that it caused also a great diminution in malaria Then again the broom was not mentioned—mosquitos during the day inhabit dusty, dark places in huts and houses. The use of the domestic broom seemed, therefore, very important.

Captain Drenger, I.M.S., said that while doing duty with European troops in India he had the opportunity of testing quinine prophylaxis. The regiment had suffered much from malaria. Therefore, at the beginning of the next malaria season, it was decided to give the troops quinine. The drug was administered in ten-grain doses on three consecutive days of each week, and this treatment was carried on for a considerable time. The result was that the number of malaria cases was greater than in any of the five previous years. The general opinion among officers was that quinine prophylaxis was useless. Certainly in this case it seemed to have had no effect.

Dr. Louis W. Sambon remarked that in discussing the value of quinine prophylaxis one should discriminate between the administration of quinine to infected persons in order to prevent the spread of the disease, and the administration of quinine to healthy men with the object of preventing them from contracting the infection. The former measure was appropriate and had already proved very useful; the latter he objected to. Quinine was the most valuable remedy we have for malaria, but it did not confer any immunity against the disease. Therefore its administration to healthy people in efficient doses, and for a lengthened period, was inadvisable. In cases of unusual exposure to the infection, he would certainly recommend the administration of quinine before any manifestation of the disease, but that would be early treatment, not prevention. The facts brought forward by Captain Drenger were in no way opposed to quinine prophylaxis. The regiment had been exposed to malarial infection for five consecutive years, the men were saturated with malaria parasites, and probably on the year of the experiment they suffered chiefly from relapses which we know cannot be avoided by the administration of quinine.

Sir Patrick Manson said he doubted the diagnosis in Captain Drenger's cases. Hitherto all fevers had been looked upon as malarial in India. He wished to draw the attention of the meeting to the introduction of malaria in new localities, such as Mauritius. There are many islands which are still exempt from malaria. In time they might become infected. We must devise means for preventing the introduction of the disease in these places.

Dr. W. J. Simpson said it was a great pity that the experiment of the Government of India had been carried out at Mian Mir. There was an error in the experiment, and one that was very likely to lead to an unfortunate result. It was known that the Government expected bricks to be made without straw. Other experiments on a much wider scale had been ordered. These experiments were to be carried out in five provinces by the local civil surgeons. But civil surgeons had no time for any scientific work in India, they had to look after so many other questions. It would be impossible for them to carry out these experiments, and he hoped they would

not try, because under the circumstances they could only do harm. If any experiments were to be carried out they should be carried out on a proper basis.

The President, Dr. Alexander Crombie, said he could not allow the discussion to close without making some remarks upon this important subject. People would look to this discussion to know what had to be done to prevent malaria. There was a lesson to be learned—the object lesson of Ismailia, where malaria was obliterated; the lesson of Havana, and the complete failure at Mian Mir. If we wanted to find the reason of the difference it was not difficult to find. If the experiment at Mian Mir had been confined to a small area, and if other mistakes had not been made, we should have had a good result. At Ismailia the anti-malarial measures were as complete as possible, and they could not have been more successful.

Third Day—Friday, July 29.

Nature and Significance of the Leishman-Donovan Body.—Major W. B. Leishman described the main facts which have been brought to light in connection with these parasites. Since the Leishman-Donovan bodies were first brought to notice quite a large number of cases had been put on record by Donovan, Marchand and Ledingham, Manson and Low, Bentley, Rogers, and others, and it was becoming more and more evident that the disease associated with their presence was by no means uncommon in tropical countries. Originally found in the spleen, the parasites had since been met with in the liver, the mesenteric glands, the bone marrow, the kidney, and in ulcers involving the intestinal mucosa.

According to Marchand and Ledingham and to Christophers, the parasite appeared to be chiefly, if not solely, intracellular, and were met with in the protoplasm of large mononuclear cells, which were probably, as Christophers suggested, "macrophages." In specimens obtained by splenic or hepatic puncture during life the parasites were, however, usually found free in groups of several members, and such free or agglomerated parasites were frequently embedded in a structureless matrix or stroma, staining gray or pale blue with Romanowsky's method. This stroma represented a fragment of the protoplasm of the large mononuclear cells which became disintegrated. The chief symptoms so far noticed in patients harboring these parasites were (1) Splenic and hepatic enlargement, the former being apparently constant while the latter was common but not invariable. (2) A peculiar earthy pallor of the skin, and in the advanced stages an intense degree of emaciation and muscular atrophy. (3) A long continued irregularly remittent fever of no definite type, lasting frequently for many months with or without remissions. (4) Hemorrhages, such as epistaxis, bleeding from the gums, subcutaneous hemorrhages, or purpuric eruptions. (5) Transitory œdemas of various regions or of the limbs. (6) Complications, such as congestion of the lungs, diarrhœa, and dysentery, had been frequently reported, and were occasionally the immediate cause of death. (7) A marked mononuclear increase, an interesting point in view of the proved absence of malaria. To these positive signs might be added certain negative ones of hardly less importance: (1) The absence of malaria, except as a concurrent affection yielding to appropriate treatment. (2) The negative result of the agglutination test of typhoid and Malta fever. (3) The resistance to medication, and especially to quinine, at all events in the later stages of the disease. The symptoms detailed above were very similar to those of kâla-azár. It was perhaps too early to say definitely that the Leishman-Donovan bodies were the cause of kâla-azár, but it certainly looked as if this were the case, as they seemed to occur constantly in this condition. If it should be so, the question arose whether the other cases in which the parasites had been found were identical with kâla-azár, and if this identity was proved, then we must admit that the geographical distribution of this disease was much wider than had been supposed, and further, that it was not uncommon among white men.

Several views had been enunciated as to the nature of the parasite: (1) Major Ross, working with films sent to him by Donovan, came to the conclusion that the bodies represented a new genus belonging to the sporozoa which he called *Leishmania*. (2) Laveran, also working with films from Donovan's cases, pronounced the bodies to belong to the piroplasmata, and gave them the name *Piroplasma donovani*. (3) They appeared to him (Major Leishman) to represent a stage in the life history of a flagellate organism closely resembling a trypanosome, if not actually belonging to that genus. Marchand and Ledingham had come to the same conclusion. Laveran's view had met with little support from other observers, whose careful search had failed to demonstrate the presence of the parasites within the red cells of the peripheral circulation. In Major Ross's view we had to deal with a new genus of the sporozoa and regard "the individual bodies as spores produced in the matrices, which would appear to be relics of the parent organism." In his first communication Major Leishman suggested that the bodies were possibly degenerated trypanosomes. Later, November 21, 1903, and February 6, 1904, he spoke of them as possible involution forms of trypanosomes or encysted trypanosomes, and as representing a stage in the life history of these organisms. Further prolonged study of the atypical forms assumed by trypanosomes had only strengthened his impression that the new bodies represented a stage in the development either of a trypanosome or of some closely allied member of the flagellata. Schander, in following the various transformations undergone by a blood parasite of the stone owl when taken into the stomach of a mosquito (*Culex pipiens*), had come to the conclusion that this parasite (*Halteridium*) was in reality, a sexual form of a true trypanosome, to which he gave the name *Trypanosoma noctuæ*. He described how at one stage the trypanosomes, free in the mid-gut of the mosquito, lose their typical shape and enter the epithelial cells of the intestine, in and among which they assume a resting form, the body becoming contracted and the flagellum shrinking up into a short rod-shaped structure. In this resting stage division by simple fission may occur, so that frequently large aggregations of these non-flagellated parasites are found in the intestinal epithelium. Further, after describing the mode in which these trypanosomes may push their way between the cells of the muscular coat of the stomach, he says, "when they come to rest here they become almost spherical and the flagellar apparatus reverts to its primitive form"—that is, to the blepharoplast or micronucleus from which it was derived. From this resting form a freely mobile trypanosome is again developed, the flagellar apparatus arising from the blepharoplast by the elaborate mitotic process whose details have been so minutely studied and described by this author. Again Prorvazek, working with a parasite of the house-fly, *Herpetomonas muscæ domesticæ*, found similar trypanosomal forms, which also assumed resting forms in much the same manner as *Trypanasoma noctuæ*. From the description and figures given by Schaudinn and Prorvazek of these resting forms of trypanosomes a very close resemblance might be traced between them and the new bodies.

A fact of great importance in connection with the possible means by which the parasites escape from the body was their presence in ulcerations of the intestinal mucosa. This fact was brought out by Christophers, and also by Manson and Low, and from the frequency with which dysenteric complications had been reported in the course of the disease, it seemed probable that this ulceration was a fairly constant feature.

With regard to the discovery of Wright, that very similar parasites were met with in the well-known Delhi boil, it was obviously of the first importance that the identity or non-identity of these parasites with the splenic bodies should be established. Should Wright's parasites prove to be identical with those under discussion there would be no great difficulty in reconciling the marked differences of

symptomatology, as bacteriology shows us so many examples of a given germ producing at one time only a local inflammatory process, at another a possibly fatal septicæmia or other grave general affection. Quite recently an announcement had been made by Captain Rogers that trypanosomes had developed in cultures of these bodies, and from the details published by him in the last number of the *Lancet* there would appear to be little doubt that this was actually the case, and that we might soon be justified in taking the connection between the Leishman-Donovan bodies and trypanosomes as an established fact.

Human Piroplasmosis.—Major C. Donovan, I.M.S., Second Physician, General Hospital, Madras, continued the discussion with a paper with this title. He said that for the present he accepted Laveran and Mesnil's determination of the organism in the genus *Proplasma*. Leishman first found the parasite in November, 1900, in smears of spleen pulp taken post mortem; he (Major Donovan) met with the parasite in the same organ, also post mortem, on the 9th of April, 1903. On June 17, 1903, he procured the parasites in blood taken by puncture from the spleen during life. Besides the spleen, the parasites were also found in the peripheral circulation when the temperature was above 103° F. (this find had been confirmed by Laveran and Mesnil), in the liver, bone, marrow, submucosa of the large intestines, ulcers of the skin, and ulcerations of the mouth; occasionally in the blood from the kidneys and suprarenals. The disease attacked the poorer classes of natives of both sexes and all castes and creeds; Eurasians and Europeans less frequently. Age was no bar to infection. In Madras the disease was chiefly endemic in the unsanitary native quarter of the city called Blacktown. The most characteristic features of this disease were an enlarged spleen, an irregular pyrexia unaffected by quinine, and the absence of the malarial parasite in the peripheral circulation. Seventy-two cases were carefully examined. The temperature was of an irregular type with occasional lapses of apyrexia. In the beginning it was of a marked intermittent type, varying from 97° to 103° or 104° F., of daily occurrence, coming on chiefly in the afternoon, associated with shivering; in the later stages it simulated hectic fever with profuse night sweats. The spleen was enlarged in nearly all cases. The increase was as a rule not great, but it varied according to the temperature in a very remarkable way. The liver was not so frequently affected in size. Diarrhœa was present in more than half the cases (40 out of 70), the motions were of a dysenteric character. This intestinal symptom was not always present, but recurred with the severity of the disease. In nearly all the cases there were skin eruptions. Sometimes there were eruptions simulating those caused by the itch mite, by the scratching of which small ulcers were formed; in two cases such ulcers reached the size of a rupee and had a great resemblance to Delhi boil. Subcutaneous hemorrhages or petechiæ were present in twelve cases, especially over the chest and ankles; outcrops of these appeared and disappeared, and were of bad augury. Pigmentation of the skin was very prevalent, noticeable usually on the palms of the hands and the soles of the feet. Another constant feature was œdema of the feet occurring in more than half the cases. Rarely was ascites found to be present. As to mortality, twenty-two died; seven were removed moribund; and with the exception of three still in hospital, the remainder were discharged at their own request, invariably in a much worse condition than on admission. In only one case was there any semblance to a cure.

The blood examinations always showed a marked decrease of the red blood-corpuscles; these varied from two to three millions to the cubic millimeter. There was no actual increase of the leucocytes, but a relative one of the mononuclears, as in malaria. The post-mortem find was generally an enlarged, pigmented, or unpigmented spleen; liver enlarged, congested, or cirrhosed; intestines, especially the large, deeply congested, inflamed, or ulcerated. Quinine had been given by mouth, hypodermically, and intramuscularly *ad nauseam*, with no appreciable result. The same might be said of other drugs, *i.e.* arsenic, salicylate of sodium, carbolic acid, creosote, tincture of iodine, etc.

Tropical Splenomegaly and Oriental Sore.—Lieut. S. R. Christophers, I.M.S., read this paper. Whoever might have first seen the parasitic bodies variously known as the Leishman-Donovan bodies, *Piroplasma donovani*, *Leishmania*, or *Helcosoma*, it was undoubtedly chiefly owing to the researches of Donovan that the occurrence of an entirely new parasitic disease of man was first brought to the attention of parasitologists and students of tropical medicine generally. Leishman's suggestion that they were any form of degenerated trypanosome was exceedingly unlikely in the face of the large number of recorded cases in which no trypanosomes had been present. The same unlikelihood pertained to their supposed affinities with the genus *Piroplasma*. On the data at our disposal it was indeed impossible to place these bodies in any of the genera or better-known divisions of the sporozoa. A good deal of speculation had raged around the nature of the so-called "matrix" of Ross, "zoöglœa mass" of Manson, and "red corpuscle" of Laveran. A study of sections showed very clearly the real condition which was one of endothelial cells gorged with the parasites. While the attention of many observers was still directed to the novelty of the presence of the bodies in the spleen and liver of cases of tropical splenomegaly, Wright in America had, apparently independently, discovered the same bodies in large numbers in the granulation tissue of tropical ulcer. Later, Captain James, I.M.S. found them in cases of "Oriental sore" from North India. Shortly after Wright's paper reached India, Donovan found the characteristic bodies in small numbers in ulcers in an advanced case of the Madras disease with enlarged spleen and cachexia. Stimulated by the discoveries of Wright and Donovan, he (Lieutenant Christophers) examined very thoroughly the tissues of fatal cases of the disease, especially with reference to the skin and intestinal lesions found in such cases. The bodies were found in non-ulcerated papules of the skin and in small and large ulcers of the skin and the intestine. They were, as a rule, scattered singly through the tissue, and appeared to be embedded in the cytoplasm of tissue cells. Closer investigation showed that they lay in the endothelial cells of the finest capillaries. No bodies were ever detected lying free in the lumen of vessels. In larger vessels, in the immediate neighborhood of granulation tissue, endothelial cells were seen containing from two to six bodies, and in many of the still larger ones cells crowded with bodies almost blocked the lumen. If we said that the disease seen in Madras is a systemic infection of septicæmic type we should most nearly express what was known as to the nature of this new protozoan disease. This view would also allow us to see in Oriental sore a local infection by the same organism.

As regards the cycle of development of the parasite, the multiplications of forms appeared to be mainly by binary fission, the larger fission forms being of secondary importance. The parasites having entered or been taken in by an endothelial cell, would appear to proliferate, causing the eventual disruption of the cell and the temporary setting free into the blood stream of the crowd of contained bodies. There did not appear to be any intracellular digestion of forms included in the endothelial cells, and the latter very probably constituted a suitable host for the parasites, in spite of the fact that it might originally take them in by reason of its phagocytic properties.

Some Notes upon Kâla-azár and the New Parasite.—Dr. Chas. A. Bentley of Tezpur, Assam, followed with a paper with this title. The discoveries of the past twelve months had now shown the connection between kâla-azár, the epidemic fever of Assam, and the so-called malarial cachexias of Bengal, Madras, and other parts of India. They had also indicated the wide-spread incidence of this

disease in many other parts of the tropics. As suggested by Christophers, the blue-staining stroma or zoöglœa mass, which was frequently to be seen enveloping masses of parasites, was in all probability derived from the large macrophages fractured in making the microscopical preparation.

In discussing the various suggestions regarding the probable nature of the Leishman-Donovan bodies Dr. Bentley said that Major Leishman's theory could not be entertained, as otherwise we should expect to find recognizable trypanosomes in some part of the human body in cases of kâla-azár. The presence of developmental forms among the new parasites entirely negatived Leishman's original view. Professor Laveran's suggestion was likewise untenable. He thought the most reasonable was that of Prof. R. Ross, who regarded the parasite as belonging to an entirely new genus.

While combating Major Leishman's view, Dr. Bentley said: "I should like to suggest that these bodies may be one phase in the life-history of some flagellate. The possibility has struck me in view of certain facts which I have been able to elect while investigating the occurrence of kâla-azár. It appears that certain species of mud fish, taken from marshes or bheels adjacent to kâla-azár infected lines, in nearly every instance showed marked trypanosomiasis. This has held good in the case of a number of different coolie lines and a kâla-azár infected village. Fishes obtained from bheels at a distance from any source of fecal contamination, on the other hand, appeared to be entirely free from trypanosome infection. I am not pursuing my investigation on these lines, but up to the present moment have been able to arrive at no definite conclusion." In the course of a long series of investigations suggested by Sir Patrick Manson, Dr. Bentley carefully examined the blood and tissues of a large number of animals of various kinds in the hope of finding some clue. He failed to find the parasite in dogs, cats, goats, cattle, rats, deer, bats, fish, frogs, and snakes. The examination of the stomach and salivary glands of mosquitos was likewise fruitless, and the dissection of several species of blood-sucking flies gave no result. Describing various researches made to discover the mode of exit of the parasite from the human body, Dr. Bentley stated that he had failed to find the parasite in any skin lesion among the natives of Assam. He said further investigations might show some connection between the local skin lesions and the general infection, but that so far the known facts appeared to indicate the existence of two different species of parasites belonging to the same genus.

Speaking of the epidemiology of the disease, he said that patients suffering from high fever appeared to be more dangerous with regard to the spread of the disease, and that cases which presented dysenteric symptoms were sure to be followed by fresh cases in the same household or among attendants. An important fact was the comparative immunity of Europeans. It indicated that certain conditions were necessary for the spread of the disease to which Europeans as a class were rarely exposed, and therefore the careful study of the case history of such patients when they were met with might be expected to give a valuable indication regarding the source of infection.

Dr. Aldo Castellani, Director of the Bacteriological Institute of Colombo (Ceylon), read a paper on "Leishmania donovani in Ceylon." He described a case of Leishmania infection in a native (Singhalese) who died of lobar pneumonia in the general hospital of Colombo. The Leishman-Donovan bodies were found in stained smear films from the spleen. They were very numerous, especially the free forms. Large numbers of leucocytes contained masses deeply stained, resembling closely the Leishman-Donovan bodies (15 to 25 per cent. of leucocytes, mononuclear as well as polymorphonuclear, presented such masses). The post-mortem examination was held less than six hours after death. No intracorpuscular forms could be seen. Castellani considered that the Leishman-Donovan bodies did not belong to the genus *Piroplasma*, as suggested by Laveran and Mesnil; he did not believe theirs to be degenerated trypanosomes, as suggested by Leishman, but thought with Ross that they probably represented a new genus (Leishmania). He further suggested that these bodies might be leucocytozoa, because in the preparations that he had examined the nuclei of the leucocytes showed very frequently masses resembling the Leishman-Donovan bodies. The bodies were far more frequently in the nucleus than in the protoplasm of the infected leucocytes, and some of the nuclei of these cells appeared to have been damaged or almost destroyed by the parasites. Castellani's case proved the existence of the disease in Ceylon, where it had not been previously observed. The case was not a typical one of tropical splenomegaly, for the spleen was not markedly enlarged.

Dr. Llewellyn Phillips of Kasr-el-Ainy Hospital, Cairo, Egypt, read a "Note on the Occurrence of the Leishman-Donovan Parasite in Arabia and Egypt." Having heard from Dr. Balfour of Khartoum that in a case at Khartoum on splenic puncture Leishman's parasite had been discovered, Dr. Phillips decided to search for the parasite in cases under his care at Kasr-el-Ainy Hospital, feeling fairly certain that some of the cases of enlargement of the spleen of doubtful etiology would turn out to be associated with the parasite in question. He found the parasite in large quantities in the splenic pulp of a Turk who had lived for a long time in Yemen in Arabia. He also found it in another patient who had lived at Mecca in Arabia, and in an Indian from Delhi. Dr. Bittes of the Sanitary Department, Cairo, to whom the parasite was shown, recognized it as identical with the one he had been shown by Dr. Sheffield Neave in slides from the Khartoum case. We must therefore add Arabia to the countries in which this parasite occurs, and since the Hedjaz was the place of pilgrimage of the whole Mohammedan world, we might have to reckon with a parasite of great import. Further, as it had been found in the Delhi boil, so it might be found in the Aleppo boil of Arabia. Taking into consideration its occurrence in Arabia and the great prevalence of chronic enlargement of the spleen in Egypt, Dr Phillips determined to look for it in the latter country, and found it in a native of the Menufiah province of Egypt in fair numbers, and also in another case of a native Egyptian in small numbers.

Dr. Leonard Rogers, Acting Professor of Pathology, Calcutta, followed with a paper entitled "Cachexial Fever in India Associated with Cunningham-Leishman-Donovan bodies." He said he associated the name of Cunningham with the parasite, in addition to those of the recent discoverers of the organism in the spleen of chronic fevers, for it had been shown by Capt. S. P. James, I.M.S., that the bodies described by D. D. Cunningham many years ago in Delhi boil were indistinguishable from those in the splenic cases. In describing the clinical features of the disease, Dr. Rogers drew attention to the fact that the temperature very frequently exhibited double daily remissions. This characteristic feature of the temperature curve was perhaps more marked in the earlier stages of the disease and might be of diagnostic value. Another characteristic feature of the disease was the remarkable and constant reduction in the number of white corpuscles. In the majority of cases they numbered less than 2,000 per cubic millimeter, but it was quite common for them to fall to 1,000 or less. The chief reduction was that of the polynuclear leucocytes; the lymphocytes and large mononuclears were relatively increased, although their total number per cubic millimeter was much below the normal. The degree of anæmia was usually only a moderate one, and might be very slight in spite of a marked white corpuscular decrease. Parasites were most numerous during marked fever. In cases with only a low intermittent fever, or none at all for days together, few parasites were found. In some cases, when they were very numerous in the spleen blood, several cubic centimeters of blood

were taken from a vein in the arm and centrifuged, but no parasites of any kind were detected in the peripheral blood by this means, so that they were probably absent from it. The recent cultivation of trypanosoma led Dr. Rogers to try to obtain similar results with the Leishman-Donovan parasite by means of adding the blood obtained by spleen puncture to a small quantity of sterile citrate-of-sodium solution to prevent the blood clotting, and then keeping it under different conditions. When the solutions were kept at blood heat the parasites very rapidly degenerated and disappeared, yet when placed in a cold incubator at 27°C. they retained their natural conditions for several days and stained perfectly. Moreover they increased markedly in numbers, so that in some instances instead of two or three in a field of an oil immersion lens, as in the freshly taken blood, after a day or two scores and even a hundred very young forms could be found in the same area. The very young forms, so numerous in the cultures, were rarely met with in fresh spleen-puncture blood and then only within large cells and not free in a gelatinous zoöglœa mass as in the cultures. The multiple forms resulted from the repeated subdivision of the nuclei of the ordinary oval form. In addition to this method of division another frequent manner was a single division of both nuclei followed by the splitting up of the parasite into two, the separation usually beginning from one end. We had, then, clear evidence of the survival and multiplication of the organism outside the body. As at a temperature of 27°C. the parasites only lived for three or four days, Dr. Rogers next reduced the temperature of the cold incubator to 22°C. This temperature was found to be more suitable to the parasites, as they multiplied more readily. Further forms of a considerably larger size appeared, and in two of the cultures unmistakable trypanosomes appeared, together with smaller pear-shaped flagellated bodies like those described by Plimmer in tsetse-fly disease. These two cultures were made respectively from a typical case of the cachexial fever of Lower Bengal and from a patient with Assam kâla-agár whose blood before incubation showed only the oval forms described by Leishman. Thus the true nature of the organism was at last clear. Major Leishman's original hypothesis that the bodies he found were degenerate trypanosomes not being very far from the truth, as they must now be looked on as one stage of the life history of the new human trypanosome found by Dr. Rogers. In this connection is was worth recalling that Assistant Surgeon Chatterji found a trypanosoma in the proboscis of a mosquito caught near Calcutta as long ago as October, 1901 (*Indian Medical Gazette*).

As to treatment, Dr. Rogers stated that he could not agree with the opinion that quinine was quite useless in this form of fever. He had frequently seen the fever stopped or greatly decreased by this drug in cases in which over 2,000 leucocytes were still present in the blood, while in chronic cases, on leaving off the drug, the fever often rose to a considerably greater height than while it was being taken regularly. Further, once the fever had been reduced a single large dose daily would often prevent a relapse. Another remedy which he recommended seven years ago, was fresh uncooked bone marrow. It was not to be expected that this substance would have a direct effect on the fever, but if this could be controlled or was mild, or absent for a time, then a more rapid renewal of the leucocytes might be brought about, the resisting power of the patient increased and recovery eventually ensue. For the prevention of the disease Dr. Rogers recommended segregation, and stated that the adoption of this measure had already been attended with success, thus demonstrating the local nature of the infection.

Sir Patrick Manson said it was certain that many medical men would be exploring spleens for Leishman-Donovan bodies. The operation was not free from danger, and as possibly the splenomegaly of other diseases might be mistaken for kâla-azár he would urge blood examination before spleen puncture. A matter of great practical importance was the settlement of the way of exit and of the way of entrance of the parasite. Its association with ulceration, dysentery, and Oriental sore suggested that it emerged through ulcerations and entered by insect bite. Oriental sore must now be regarded as a serious disease, sometimes leading to a general infection.

Dr. Louis W. Sambon, in lectures to the London School of Tropical Medicine, said that when he first saw the Leishman-Donovan organisms, in the preparations sent by Major Donovan to Sir Patrick Manson, he was struck with their resemblance to some of the so-called amœboid forms of trypanosomes which he had the opportunity of examining in Dr. Castellani's preparations. The presence of a well-marked blepharoplast in close proximity to the nucleus of the organism seemed an indubitable proof of the flagellate nature of the parasite. The observations by Major Leishman, Major Rogers, and Dr. Castellani seemed to show that the Leishman-Donovan bodies in man were chiefly found within the leucocytes, and in this respect resembled the so-called leucocytozoa of birds. He had no doubt that the study of the Leishman-Donovan parasites would help us to elucidate many obscure points in the pathology of sleeping sickness. As to the transmission of the new parasite, analogy would incriminate some of the dipterous insects, and he thought very careful investigations should be made on this point.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 27, 1904:

	Cases.	Deaths.
Measles	70	4
Diphtheria and croup	244	25
Scarlet fever	48	2
Smallpox	...	...
Varicella	3	...
Tuberculosis	371	147
Typhoid fever	140	27
Cerebrospinal meningitis	...	17

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended August 27, 1904:

SMALLPOX—UNITED STATES.

		CASES	DEATHS
Georgia, Macon	Aug. 13–20	1	..
Illinois, Chicago	Aug. 13–20	6	..

THE CYCLE OF THE TUBERCLE BACILLUS.

A PRELIMINARY ANNOUNCEMENT.

By STEPHEN J. MAHER, M.D.
NEW HAVEN, CONN.

On the first day of last May, after several weeks of unsuccessful efforts to secure pure cultures of an acid-fast bacillus that I had found in a dark barn, my attention was attracted by an organism that grew, apparently in pure culture on media where only forty-eight hours before I had planted almost a pure culture of the elusive acid-fast. This new organism was at least ten times as large as the tubercle bacillus. It occurred in chains and single, and was the largest bacillus that I had ever seen. It contained much granular spore matter of varied shape, and, a thing that appealed to my fancy, some of this spore matter was consistently acid-fast.

During the next few weeks, I grew the organism in all sorts of media. I found that the contained spore matter, though it could not be readily made to develop into rods that looked like tubercle bacilli, could very easily be changed in forms very unlike that of its mother bacillus, and that the mother bacillus itself could be made to change its size and spore content, by the addition of various chemicals to the culture media in which it was growing.

I had observed that the original infusion of barn scrapings in which the acid-fasts still continued to thrive, was strongly alkaline. I therefore made several hundred alkaline experiments in which the medium was rendered alkaline by the addition of ammonia. I was frequently rewarded by finding acid-fasts, an occasional rod or small group of rods, or crescentic or ovoidal spores, but usually when on the next day I took smears from the same tubes not an acid-fast could I demonstrate. I thought at first that there was something wrong with the staining technique; but after much floundering, I finally reached the conclusion that the short exposure of the tubes to the bright sunlight of the laboratory was the cause of the disappearance of my acid-fasts. I observed that the mother bacillus found blood serum and thoroughly sterilized milk the most favorable media for the development of its acid-fast children. Still even in these media there was more of promise than performance—that is, in many tubes there were acid-fast rods of good and indifferent shapes but they were few as compared with the number that I could always get in a smear from the bottle of alkaline hay infusion in the incubator.

On June 21 I examined a tube of milk that had been planted with the mother bacillus on May 4, and made alkaline with three drops of ammonia on May 28, and later discarded as giving rather unsatisfactory results. It had been standing for two weeks in a dark corner of the thermostat room. To my great joy, I found that every field of every smear now gave masses of beautiful acid-fast rods, usually arranged in clumps, and that about these clumps were large blue rods and ovoids of my *Bacillus maternus* usually containing acid-fast spore matter, of rosette shape or amorphous. The next day, I made other smears from this tube, and found the acid-fasts still there. I then poured an equal amount of sterile bouillon into this tube, and injected ten minims of the mixture into each of ten guinea-pigs, intraperitoneally. The syringe and needles were new, and were boiled for half an hour before using. At the same time in the conduct of other experiments, I injected—of course, with other syringes—tubercle bacilli into twenty-seven other pigs. The first of the thirty-seven to die was one that had been injected with the progeny of *Bacillus maternus*. It died on the twenty-fourth day. On autopsy it was found to have four tubercles in the mesentery, sixty in the liver, an enlarged caseous spleen and enlarged and soft suprarenal capsules. Acid-fast rods and ovoids and crescents were demonstrated by the microscope in smears from tubercles in the liver and mesentery and from the pus from the suprarenal capsules.

Another pig of the series died on the fifty-second day and was also tuberculous. The other eight were killed, one on the twenty-seventh day; one on the forty-fourth day; two on the fifty-first day; two on the fifty-fourth day; and two on the fifty-ninth day. Of these none had so many tubercles as the one that died first, but all were tuberculous. In two the only evidence of the disease was in the spleen. A control pig, killed at the close of the experiment, showed no sign whatever of tuberculosis.

After the injections on June 22, I took the tube of mixed bouillon and infected milk and put it in the incubator at 37.5° C. The next day I found that smears taken from it showed a considerable change. There were still many large mother bacilli and acid-fast rods and small ovoids; but the rods seemed a little thicker than tubercle bacilli. And there were in every field many granular blue rods not more than a quarter as large as the mother bacilli. The following day the proportion of acid-fasts was much smaller, and they were generally crescentic or ovoidal in shape. I found now at the bottom of the tube a few blue biscuit diplococci and a few segmented large rods. The scum contained no long bacilli materni, but many of the granular blue rods found on the preceding day.

By July 5 the acid-fasts had entirely disappeared from the tube, which still contained a few mother bacilli large and small, and many biscuit diplococci in twos and fours, and some in lines of five and six.

On blood serum and milk, *Bacillus maternus* reproduces itself by fission, at the same time depositing acid-fast spore granules, large ovoids, rings, and rosettes. The rings and rosettes swell, and under favorable conditions are seen to contain small ovoids and crescents and blunt rods. The large ovoids reproduce large granular rods. The small ovoids and crescents, and blunt rods will, in suitable environments, become acid-fast rods, indistinguishable from tubercle bacilli.

Very often in a medium that is unsuitable for the full development of the large mother bacilli rods, a number of the segments roll together, and from this ball small non-acid-fast biscuit-shaped diplococci make their way. Often, again there will be seen segments of vigorous adult mother bacilli in which the contained

granules of spore matter have taken on the shape of these biscuit diplococci.

I have several times planted bacilli materni on blood serum the surface of which had been two days previously treated with ammonia. The resulting growth contained beside the adult bacillus maternus lancet-shaped diplococci and no biscuits. I have with the proper precautions taken bits of the fresh spleens of guinea-pigs infected with *Bacillus maternus* and dropped them into tubes of sterile milk. In glass-slide smears, taken from the same spleens, no organism, or only a few acid-fast rods and crescents, could be found; but in twenty-four hours the tubes of milk were filled with non-acid-fast cocci, which soon became diplococci, and then biscuits, and then gave place to non-acid-fast granular rods larger than tubercle bacilli, but resembling them in shape and in the disposition of their contained granules. After these milk tubes had been three days in the incubator at 30° C, I found in them beautiful clumps of large bacilli materni. I have said that smears direct from the spleens gave no bacteria, but I must add that they did give a very interesting something—masses of granular matter, amorphous or made up of poorly shaped ovoids, and which stained orange or orange and black with Gabbett's stain, which sometimes swelled out a blood cell like a malarial crescent, but was oftener found free in the spleen tissue. I am convinced that it was from this yellow spore matter that the blue cocci came, and that this yellow spore matter was the last retreat of the vital spark that had been conveyed to the spleen in the acid-fast rods which were there destroyed. I have found the material invariably in the spleen and occasionally in the liver of tuberculous guinea-pigs, in cultures of tubercle bacilli in bouillon, in various cultures from tuberculous sputum, in smegma, and in ear-wax that contained acid-fast rods.

On July 10 I planted a pure culture of tubercle bacilli in a tube of sterilized milk and placed it in an incubator in which the temperature ranged from 30° to 35° C. The culture had been secured from Dr. E. R. Baldwin in February and since sub-cultured on glycerin-agar. It was the comparatively non-virulent culture known as the "K Culture" at the Trudeau laboratory. Every day or two afterward I exposed that milk tube to the light of the laboratory window for perhaps thirty seconds, and gave it a gentle shaking. On July 22 I made a sub-culture from this tube into another milk tube. On July 23 I made smears from both of these tubes. I found that both tubes contained very long granular acid-fast tubercle bacilli and a very few bacilli morphologically the same but not acid-fast. There were a few blue biscuit diplococci, and one blue tetrad free in the field. The thing that caught my attention most strongly was the biscuit shape of the granules in the tubercle bacilli. I had not seen that phenomenon before. The blue rods, of course, might have been the result of too long a decolorizing. Perhaps this is as good a place as any to explain that in all the work described in this paper the staining was done by the Gabbett modification of the Ziehl-Neelsen fuchsin-and-methyl-blue method, and that I carefully refrained from sealing the cotton plugs of tubes and flasks with paraffin or wax. I was astonished to find that there had been such a rapid growth of tubercle bacilli in the second tube after only twenty-four hours' incubation. Every loopful of the milk seemed to contain as many bacteria as had been originally put in the tube.

That night I poured a tube of sterile milk into two thoroughly sterile ground-glass-stoppered bottles, and in one planted tubercle bacilli from the milk tube of July 10, and in the other tubercle bacilli from the tube of July 22. Twenty-four hours later, I found that the "July 10 sub-culture" contained only acid-fast but very granular and long tubercle bacilli, and that the granules were rod shaped or biscuits; and that the "July 22 sub-cultures" contained only a very few acid-fast tubercle bacilli but thousands of blue biscuits in all sorts of groupings, and beautiful large bacilli materni, and round clumps of blue spore matter. I realized that there was nothing conclusive about this experiment, but it was startlingly suggestive. In following up the suggestions that it offered, I have spent much time and effort since. I cannot here describe in detail my experiments, important though I think them to be.

Most of my work was done with milk, and I know milk as a culture medium is not beloved of bacteriologists, but the results that I shall narrate were all achieved with absolutely sterile milk, as proved by controls. One supply of milk, I found it very hard to sterilize. There were still germs in it after it had been steam sterilized for an hour on three successive days and had besides been given half an hour in the autoclave at 120° C. Much of the work was done with milk to which an equal amount of boiled filtered water had been added, and which had then been kept in the hot air sterilizer at 160° for an hour on two successive days. I found it impossible to prevent milk from burning if kept for an hour in the autoclave at 160°.

Pure, strongly virulent tubercle bacilli, taken July 30 from a blood-serum tube fresh from Saranac Lake and planted in browned-milk tubes, gave after twenty-four hours and after forty-eight hours nothing but acid-fast tubercle bacilli; but a sub-culture, made after twenty-four hours, in a flask of milk that had been browned in the autoclave, gave twenty-four hours later a pure culture of a large blue granular rod exactly like one form of *Bacillus maternus*.

A pure culture of the more vigorous but less virulent K-culture of Saranac Lake, after the same procedure, gave a few poorly acid-fast granular tubercle bacilli, and many blue rods containing distinct biscuit granules and many blue masses formed of clumped and disintegrating tubercle bacilli

This brings me to another interesting point. Under certain conditions of unfavorable environment which I do not pretend to understand, tubercle bacilli instead of continuing on the return half of the cycle to mother bacilli retrogress by one of several longer courses. In the first one, they clump and lose their acid-fast property. A deeply stained small ovoid appears in the center of the now homogeneous mass. This mass becomes more opaque and rounded and takes on the appearance of the nucleus of a pus cell. From this body may come, according to the demands of environment, one large *Bacillus maternus* or many non-acid-fast cocci or biscuit diplococci. If the latter should be the event, still another side road must be traversed before *Bacillus maternus* is reached. The diplococci must stretch out into small rods, the rods must become chains, and the links in the chains must grow to the size and content of bacilli materni. A second way in which tubercle bacilli complete their life cycle in this: the round granule or bead that has been so often observed at one end or in the middle of the supposedly dying bacillus swells enormously, detaches itself from the shred of the rod from which it came, and itself becomes non-acid-fast. As it enlarges, it evolves four deeply staining nuclei and either breaks up into tetrads or biscuit diplococci, or assumes the shape of a pus nucleus or of a large ovoidal spore. The third route is for the tubercle bacillus while still

acid-fast to enlarge until it contains three equal square-ended solidly staining bodies. These pull apart somewhat, and lose their acid-fast property, and by some strange attraction gather about them opaque masses of protoplasm, and, in a few hours they are the centers of the three poorly divided segments of what looks like the crescentic nucleus of a pus cell.

A fourth way is for the tubercle bacillus to enlarge quickly along its own lines, and even before it loses its acid-fast property, to display varied granular contents. I have seen in one enlarged acid-fast rod a well-defined crescent, a short rod, a biscuit diplococcus, a monococcus, and an ovoid.

I have found it possible, but not easy, to reduce tubercle bacilli to bacilli materni without the use of milk. I have succeeded best by quick transferances from bouillon to potato and back to bouillon. Even at the potato stage of this progress, I have discovered nests of tubercle bacilli, growing among the slightly larger non-acid-fast granular rods, characteristic of one stage of the first half of the cycle.

On plain bouillon, a culture of the less virulent tubercle bacillus, kept at 30° to 35° for two weeks, gave acid-fast tubercle bacilli, about a dozen, small and deeply stained, to a field, and occasional clumps of small blue rods with an ovoid spore shining through. These groups tended to rotundity of form and suggested pus nuclei or poorly shaped spores of *Bacillus maternus*.

Pure tubercle bacilli planted in milk tubes July 21, kept at 30° for twenty-four hours, and then subcultured in bouillon, showed after twenty-four hours a few tubercle bacilli of good shape, but most of the bacilli, though still acid-fast, were breaking in two, both halves becoming ovoids. There were also many very large rods becoming granular and suggesting medium-sized bacilli materni. Two days later there were still a few acid-fast rods, but the large rods had become deeply blue and attained the exact size and appearance of large bacilli materni.

I am unable yet to formulate rules for the certain conduction of tubercle bacilli back to their mother shapes The subject is very much involved, and has to do probably with the vitality of the culture, the degree of acidity and aëration of the medium, its density, and the amount of light it is capable of absorbing. There seems to be a constant struggle in a milk culture of tubercle bacilli between two tendencies of the germs, one simply to reproduce themselves, and the other to complete their larger cycle. Sometimes in media in which on one day it is possible to find with the Gabbett stain, a few blue biscuits or rods mixed with the acid-fast tubercle bacilli, on the next day there will be nothing in the smears but the tubercle bacillus.

This was rather dramatically shown in the following experiment: On the morning of August 19 I made smears from two flasks that had been six days in the thermostat at 30° to 35°. Flask No. 1 had been planted with pure tubercle bacilli from a glycerin-agar tube on August 13. No. 2 had been planted on the same day with tubercle bacilli that had been growing ten days on milk since leaving the same glycerin-agar tube. Both flasks were found to contain immense quantities of granular acid-fast tubercle bacilli and nothing else. Flask No. 1 seemed to have the greater number of bacilli. I placed both tubes on my desk between two western windows. Four and one-half hours later, I again made smears from both flasks to see whether the exposure to light, and room temperature, had yet effected any change. There was still nothing but tubercle bacilli in either flask, but on one smear from flask No. 2 a few fading clumps were forming. After twenty-four hours more, during which the flasks had still been on my desk, I took other smears and found that in flask No. 1 there were now as many large shapely bacilli materni as there were tubercle bacilli. In flask No. 2 there were only a few bacilli materni not more than a dozen in a smear, but not on any day since have I been able to find a single blue-stained organism in any of the smears I have made from flask No. 2. From flask No. 1 I have grown beautiful sub-cultures of *Bacillus maternus* on blood, potato agar, and bouillon. Why the process of evolution was stopped in one flask and not in the other, I cannot understand. In both these flasks only a thin layer of milk was used. The milk was from a different dairy from any that had heretofore supplied me. The flasks had been subjected to 160° dry heat, for more than an hour. The milk had been subjected to 160° for an hour on two successive days and then steam-sterilized for an hour. The controls showed no organisms of any kind. The college janitor, an entirely reliable man, and myself were the only persons who visited the laboratory during the twenty-four hours in which this transition from tubercle bacilli to bacilli materni, took place in those flasks. Nobody but myself knew what was in the flasks nor what was the purpose of exposing them to the light.

I have not yet been able to grow a pure colony of *Bacillus maternus* from tuberculous spit, but I am satisfied that I have several times recognized individuals and groups of this organism in the fields of blue biscuits and pus nuclei and acid-fast rods, that we are all familiar with. I have isolated a pure culture of what seems to be *Bacillus maternus* from smegna. I have grown it from the spleens of guinea-pigs dead with tuberculosis.

The constant association of biscuit diplococci with the acid-fast rods found in smegna, in hay, in manure, in butter, and in tuberculous lesions is an interesting point.

Before concluding I would like to return for a moment to the technique of deducing acid-fast rods from *Bacillus maternus*. I found last spring that in the shay and manure I gathered from the dark barns there were many active yeasts. It occurred to me that perhaps the alcohol or ether, the result of yeast growth, might be helpful if not essential to the development of the small acid-fasts. After some experimentation, I concluded that the best results were obtained by the following formula: Plant pure *Bacillus maternus* in milk tubes. Place these in the incubator for two weeks. Add two, or not more than three, minims of ether and the same amount of ammonia to every 6 c.c. of milk. Replace the tube in the incubator for two days, and then put them in the dark at room temperature for two days. This does not always succeed; but the results in the way of getting grouped acid-fasts are often very striking. Why does it not always succeed? I do not know, but it must be remembered that milk is a fluid of very variable chemical composition. Particularly true is this statement of skimmed milk. And it is skimmed milk that it is necessary to use as a medium. It is not greatly to be wondered at that a process so sensitive to light and air as I have found the formation of these acid-fasts to be, should also be interfered with by too much fat or too little, or too much sugar or too little, or too many or too few of the toxins or the antitoxins of dead bacteria in the tubes of skimmed milk in our incubators.

Some tubes of milk from which a few weeks ago I could get thousands of beautiful acid-fast rods with every loopful of milk, I find to-day contain not one satisfactorily acid-fast bacillus. They had been

exposed to much reflected light and no ammonia or ether had been added to the milk for weeks.

Bacillus maternus is unquestionably one of a large family. I have found several other bacilli that resemble it greatly; but at their largest they are somewhat smaller than it at its largest. One of these I have found in milk, another grew on agar plates exposed at Saranac Lake on the coldest day of last winter; another, I isolated from a common thistle picked up on the parade ground at Fort Stanton, New Mex., last February; another came from a climbing Japanese vine that shut out the light from the farm-house bedroom of a consumptive girl of healthy stock and association; another came from the skin of a Japanese variety of plum that arrived, carefully packed, from South Africa last winter. These organisms differed in many respects from *Bacillus maternus*, but they had in common with it, the property of voiding, besides the ordinary large more or less acid-fast spores, certain rosettes or asters or rings of acid-fast spore matter, which under favorable conditions had the faculty of becoming small rods or biscuit diplococci. They all contain at certain stages of their rod development granules of differing shapes, some of which are acid-fast. They form colonies of similar shape on agar and blood serum.

Bacillus maternus is a large bacillus, the individual rods from blood or milk measuring three to eight microns in length and three-fourths to two microns in width. One average rod would cover a dozen average tubercle bacilli. It is a non-motile, facultative anaerobe. It forms a sediment and scum on bouillon and renders it turbid. It forms an opaque non-spreading colony on the surface of agar or glycerin-agar in tubes or Petri dishes. Deep colonies in agar resemble those of anthrax. It grows at room temperature and its spores resist more than one hundred degrees of moist heat for an hour. It digests but does not curdle milk. It forms a sunken colony in blood serum and only slightly digests the serum. It quickly dissolves gelatin and shrinks to smaller rods. On ammoniated gelatin the rods are somewhat stouter with a growth of diplococci. After fifty hours on sugar gelatin the colony consists of many larger spores and an immense amount of acid-fast amorphous spore matter which fills to bursting many of the rods, and which is also found in various rounding shapes free in the microscopic fields. On potato a dry opaque gray or lemon-colored growth is formed.

212 Oran.e Street.

The Vomiting Sickness of Jamaica.—R. S. Turton gives a vivid picture of this affection. The disease occurs only in the cold months, being rarely seen before December or after March. It occurs in country districts, not in towns, among the poorer classes and unhealthy surroundings. The writer can recall few or no fatal cases occurring in properly ventilated houses. The disease may attack more than one member of the family either at the same time or at intervals of hours up to a day or two. It attacks children, usually irrespective of sex, presenting a longer or shorter period of malaise, followed by vomiting, convulsions, and death in a few hours. Post-mortem examination reveals signs of gastrointestinal irritation, and usually infection with ascarides in large numbers. The writer believes that the disease is caused by a toxin affecting the respiratory center. It kills by respiratory failure. There is a very small death rate in cases in which early treatment has been given. Early and free stimulation, warmth, followed by a dose of calomel and castor oil, will probably avert any ill effects; but to be of use, the remedies must be administered before the convulsive stage sets in.—*The Journal of Tropical Medicine.*

CLINICAL AND OTHER FEATURES OF THE RECENT EPIDEMIC OF CEREBROSPINAL MENINGITIS.*

By HENRY W. BERG, M.D.,
NEW YORK.

VISITING PHYSICIAN TO THE WILLARD PARKER AND RIVERSIDE HOSPITALS; ADJUNCT PHYSICIAN TO MOUNT SINAI HOSPITAL; INSTRUCTOR IN INFECTIOUS DISEASES, COLUMBIA UNIVERSITY.

In April, 1894, I read a paper before the Pediatric Section of the New York Academy of Medicine, recounting the clinical features of an epidemic of cerebrospinal meningitis which had occurred in New York City during 1893, lasting from March to July, there having died in May, 1893, at the height of the epidemic, 107 cases. At all times the disease is endemic in New York, the average number of deaths being, for Manhattan and the Bronx, in late winter and spring 25 per month; sometimes as low as 10 during the fall and early winter.

The number of deaths from cerebrospinal meningitis in Manhattan and the Bronx from January 1, 1904, to June 4, 1904, was as follows:

Week	Jan.	2	5	Week	April	2	25
"	"	9	5	"	"	9	22
"	"	16	5	"	"	16	42
"	"	23	5	"	"	23	45
"	"	30	6	"	"	30	52
"	Feb.	6	5	"	May	7	53
"	"	13	2	"	"	14	73
"	"	20	3	"	"	21	69
"	"	27	4	"	"	28	54
"	March	5	5	"	June	4	52
"	"	12	4				
"	"	19	14				
"	"	26	19				

It will be seen that the number of deaths from this cause rose from 24 in January, and 14 in February, to 33 in March, and 306 in May; in the last month more than twelve times the average number of deaths from this disease during non-epidemic years. These figures prove that the present epidemic is much more severe than that of 1893, even allowing for the increase in the population of the city. From my study of the statistics of this disease, both in 1893, and the reported statistics of the epidemic in Lisbon in 1900, I found that when during the epidemics there was for three or more successive weeks a decided decrease in the number of deaths it was generally found that the high figures before the decrease represent the acme of the epidemic, and that a continuance of the gradual diminution in the number may be expected. I speak of this because it yields the one encouraging factor in the above figures which show that the largest number of deaths (73) occurred in the week ending May 14, and the four subsequent weeks represent a steady decline to 52, during the week ending June 4. If then, in this respect, this epidemic follows the course of former epidemics, we may hope that the disease is on the decline. This epidemic is far more general in its geographical distribution than that of 1893. The statistics of the State Board of Health show a large increase in the number of deaths from this disease throughout the State, while in New Jersey and Connecticut the number of cases is very much increased.

The present epidemic is no exception to the usual rule observed in all epidemics of this disease, that it has a predisposition for infants and young children. Four hundred and eighty-one out of 750, more than three-fifths of the deaths, occurring in the greater City of New York from January 1, 1902, to June 4, 1904, were of children under six years of age. Nevertheless, the proportion of older children and adults dying from this disease in this epidemic is *very much greater* than in any other epidemic the statistics of which I have seen.

*Read before the Medical Association of the Greater City of New York, June 13, 1904.

Indeed, in the epidemic of 1893, adults were almost entirely free from the disease. The following figures, furnished me by Dr. W. H. Guilfoy, Register of the Department of Health, and for which I desire to express my thanks, show that 125 out of 750 were over twenty years of age—an extremely unusual proportion of adults. Moreover, in my own experience in this epidemic, the cases affecting adults and older children were far more severe. One adult whom I saw with a colleague was brought home from his shop in convulsions, and died within thirty-six hours. He had complained, for only twenty-four hours before the first convulsion, of headache and pain in the back of the neck.

In this epidemic, as well as in the epidemic of 1893, a very large increase in the number of deaths from pneumonia has been observed, occurring synchronously with the existence of the epidemic of cerebrospinal meningitis. This has been true of all the recorded epidemics of the disease in this country. The largest number of cases occur during the cold and wet seasons of the year, although the disease, being chronic, the largest number of deaths takes place one or two months later. This fact is of extreme interest from an etiological standpoint.

It is known to all of you that the bacteriological cause of epidemic cerebrospinal meningitis is the diplococcus intracellularis meningitidis isolated and culturally and morphologically described by A. Weichselbaum and his pupils and followers. And yet, in a publication in 1887 even Weichselbaum conceded that a proportion of the cases of epidemic cerebrospinal meningitis were due bacteriologically to the diplococcus pneumoniæ, which also was the most frequent etiological factor in idiopathic cerebrospinal meningitis. At that time he conceived that it was possible for the diplococcus intracellularis meningitidis to produce epidemics of cerebrospinal meningitis. That this germ is the exclusive bacteriological cause of such epidemics was not claimed by bacteriologists or clinicians until the work of Jaeger (*Zeitschrift fur Hygiene*, Bd. 19, 1895). It is curious and interesting, however, that the culture behavior and morphological characteristics of the diplococcus intracellularis meningitidis, as found by Jaeger, differed in important respects from the description of Weichselbaum. Many authorities before this had considered the Weichselbaum meningococcus simply a specialized variety of the pneumococcus, and many had considered it identical with the diplococcus pneumoniæ of Frankel.

Netter in 1898 (*Bulletin et Mémoires de la Sociète de Medicin des Hôpitaux de Paris*, 1898, 13 and 20 May), in a small epidemic in Paris found diplococci which, after repeated passage through white rats took the typical form of diplococcus pneumoniæ. Such reports of large material as those of Councilman and Mallory and Wright in Boston (111 cases, 1897), Faber (60 cases in Copenhagen, 1898, and Bettencourt and Franca in Lisbon, 271 cases), in all of which the Weichselbaum meningococcus was found in the cerebrospinal fluid obtained by lumbar puncture, are conclusive of the individual identity of this organism and its etiological importance in this disease.

Whether it is the exclusive cause of all epidemics of cerebrospinal meningitis, appears to me still unproven.

This even Weichselbaum acknowledges, especially when it is remembered that there are different types of organisms which have been found in various cases of sporadic and even epidemic cerebrospinal meningitis; not only the two mentioned, but the streptococcus pyogenes, and also the staphylococcus pyogenes, while sporadic cases of tuberculous cerebrospinal meningitis are, perhaps, the most frequent form of that disease.

Meanwhile, I repeat, that the fact that epidemics of cerebrospinal meningitis in this city have been accompanied by a simultaneous increase in the number of pneumonia cases is an important and pregnant one. It is interesting to note that one of my earliest cases in the present epidemic of cerebrospinal meningitis, a girl of eighteen, had an attack of typical lobar pneumonia involving the upper lobe of the right lung. On the third day of the disease opisthotonos with cerebral symptoms (dilated pupils, delirium, convulsions) developed. The pneumonia went on to resolution after six days, but the cerebrospinal symptoms continued; a lumbar puncture yielding 15 c.c. of a turbid fluid showed the diplococcus intracellularis meningitidis. This case died after four weeks. It was clinically an undoubted case of lobar pneumonia complicated by or complicating epidemic cerebrospinal meningitis.

In the epidemic of 1893 I could not find any history of more than one case in one family; none occurred in my own practice. Councilman writes that in the Boston epidemic the same was true, the cases occurring in different and distant parts of the city among the poorer population. In the present epidemic my experience has been different; the cases I have seen in my private practice—about twenty in number—have been almost all in the lower and east end of the city, although the Health Board returns show that the epidemic has been quite general throughout the city among the tenement population in the thickly settled districts. Cases have been quite numerous in Brooklyn. Furthermore, among my own cases I have a family in which the three children were all taken with the disease; two of them have died, and one is still very ill. The first child died the first week in May. The second child was taken ill a week later, and died the first week in June. The third and oldest child, a boy of eight, is still sick. These were undoubted cases of epidemic cerebrospinal meningitis.

A mother died of epidemic cerebrospinal meningitis in the hospital. The daughter (adult) attended the funeral, was taken with severe headache the same evening, and brought to the hospital several days later suffering from cerebrospinal meningitis. I know of two other instances in which two members of the same family were taken with the same disease.

While these cases seem to point to the contagious character of the disease, we know nothing of the incubation period of the disease, and but little of the method of the spread of the contagion. It is generally conceded by most clinicians and bacteriologists that the germ probably enters through

DEATHS FROM CEREBROSPINAL MENINGITIS IN THE GREATER CITY OF NEW YORK FROM JANUARY 1, 1904, TO JUNE 4, 1904:

Total	Males	Females	Under 1 Year	1	2	3	4	Total under 5 Years	5	10	15	20	25	30	35	40	45	50	55	60	65	70
750	416	334	80	74	51	49	58	312	169	74	71	40	22	19	11	8	12	4	2	4	1	1

the nasal passages, and is spread by the lymphatics to the dura and subarachnoid spaces. It is possible, also, that the organism is carried by the capillaries to the site of the lesion in the brain and spinal cord, although a general infection of the blood, septicæmia, does not occur, nor has the organism been found in cultures taken from the blood (Councilman).

The germ can be frequently isolated from the nasal discharges from patients suffering from the disease, and it is very possible that it is spread in times of epidemics by the nasal and conjunctival discharges from the sick. These are carried either directly to the attendants who handle the soiled, wet handkerchiefs and towels from the sickroom. Or, the discharges drying in the sickroom, and on the clothing and bedding of the patient, are carried in the currents of air, and are inhaled into the nostrils of healthy subjects. Where a fitting nidus is found, contagion may thus take place. I do not think the danger of contagion is as great as in pneumonia, which I consider to be only slightly contagious, and then only through the sputum.

It is interesting to note here that most observers, among others Councilman, have found that the diplococcus is of feeble growth, and frequently large amounts of cerebrospinal fluid must be used to produce a positive culture, which may be one of the elements that would account for the rarity of contagion.

On the other hand the organism is one of the most resistant to drying agencies, retaining its life for a long while. Jaeger (*Deutsche medizinische Wochenschrift*, 1894, No. 18) was able to isolate the diploccocci from a handkerchief that had been used in a sickroom of a case of cerebrospinal fever six weeks before. Experiments made by Eduardo Germano (Die Uebertragung von infectiösen Krankheiten durch die Luft; *Zeitschrift für Hygiene*, 1897, Vol. 26, p. 29) showed that when the meningococcus is dried rapidly or slowly, it is one of the most resistant organisms, so that as a dust it can readily be carried in the air, and in this way produce infection. Cleanliness in the sickroom, the careful removal of the discharges from the patient's nose and eyes by cloths, and pieces of gauze which can be destroyed, the separate boiling of towels, clothing, and bedclothes, and the careful and frequent washings of the hands of the visitors and attendants, will be sufficient safeguards to prevent the immediate carrying of the contagion from the sick to the healthy, and will leave no nasal discharges to dry in the sick room, and thus cause an indirect contagion through the air. The infrequency of these epidemics, and the comparatively short duration of each (a few months) indicates that the instinctive precautions of the above nature, which we take to protect ourselves against all infectious diseases, even when their contagious character is doubtful, have been sufficient in all previous epidemics. Nor do I think that this disease is as contagious, directly or indirectly, as typhoid fever is through the stools, or even as pneumonia is through the sputum.

For the purpose of bacteriological diagnosis of the disease during life the meningococcus must be sought for in the cerebrospinal fluid obtained by lumbar puncture. It can be demonstrated by culture and microscopically. Cultures made from fluid obtained by lumbar puncture early in the disease will give positive results in a very large proportion of cases. Bettencourt and Franca found it in the Lisbon epidemic of 1900 in 271 cases out of 271 examined. It was never found by them in the blood during life. The blood serum of those sick and those who had recovered has agglutinating properties In six cases examined by Franca two responded in the proportion of 1 to 100, the remainder 1 to 10, 1 to 20, and 1 to 50. Whether the agglutinating reaction will be found to be sufficiently reliable and exclusive to use the method for diagnostic purposes, after the manner of the Widal reaction in typhoid fever, remains to be seen. The diplococcus can also be found in the nasal discharges of patients suffering from the disease, both microscopically and by culture. Weichselbaum, however, quoting Albrecht and Gohn (*Wiener klinische Wochenschrift*, 1901) states that there is some doubt as to the identity of the diplococci found in many of the cases. If lumbar puncture is done early in the disease, a cloudy fluid will be obtained containing pus cells in which the organisms are found; later in the disease, with a clearer cerebrospinal fluid the result may be negative. Diplococci are more apt to be found in fluid obtained during the acute stage or during an exacerbation.

For the purpose of studying the symptomatology of the cases in this epidemic, I will remind you that the locus of the lesion of this constitutional acute infectious and to some extent contagious disease is in the membranes of the brain and spinal cord. The lesion is primarily a leptomeningitis involving the pia mater and the arachnoid, although in the progress of the disease the inflammation extends into the substance of the brain and spinal cord, giving rise to purulent infiltration and even abscess of the brain and cord structure both in the gray and white matter. In some, fortunately rare cases, the ventricles of the brain and the central canal of the cord become filled acutely with a purulent or seropurulent effusion. In the brain and cord of severe cases there is a general purulent inflammation, resulting in changes of a destructive character in the nerve fibers and ganglion cells and proliferation of the neuroglia. The lesion, however, is primarily located in the membranes of the brain and cord, and the involvement of the spinal-cord membranes is much greater and more general than in any form of meningitis. The popular name of the disease, spinal meningitis, is not a misnomer. The lesion extends along the base of the skull to the cranial nerves, particularly the auditory and optic nerves, and the fifth nerve ganglia; no cranial nerves, however, are exempt.

The frequency of severe and permanent lesions of the eyes and ears is the result of the extension to and infection of the optic and auditory nerves. Wherever the infection extends there the diplococcus can be found. The infection also extends into the spinal nerve roots and spinal nerves, giving rise to symptoms depending upon inflammations and degenerative changes in these nerves. Inflammation of the lungs, bronchi, tonsils, and middle ear are met with due to the direct invasion of the organism by extension from the nasal cavity and meninges of the brain.

In this epidemic the cases I have seen can be divided into three classes:

Most frequent, the *chronic cases*, beginning with acute symptoms which gradually subside and become chronic in character. All of these cases have acute exacerbations, in any of which they may die, or the symptoms may again subside and resume their chronic character—after weeks and even months of illness these cases may die, or they may recover completely or they may recover with more or less complete and permanent disabilities of the eyes or ears, sensory and motor paralyses or more or less extensive psychical disturbances.

2. The cases next in frequency, which are

throughout their course of an *acute* character, much shorter in duration than the chronic cases, lasting from one to four weeks, and terminating either in death or absolute recovery. In these cases sequelæ are rare.

3. The *fulminating* cases, of which I have seen two in my practice in this epidemic, which last from a few hours to three or four days, are characterized by most foudroyant symptoms and terminate in death.

The abortive type of cases, lasting for a few hours or a day or two, with recovery, I have not seen in this epidemic, probably because I do not consider the diagnosis confirmed until the diplococcus has been found in the fluid obtained by lumbar puncture.

In all three classes of cases in this epidemic the onset has been acute and sudden, and that is true of all the cases of which I have heard from others. The disease in this epidemic has had no prodromal stage. The acute symptoms have been those of a febrile disease involving the brain and spinal cord; they have consisted of severe headache, pain and stiffness and even rigidity at the back of the neck and in most cases in adults, and in all cases in children, vomiting. With these symptoms there was in almost every case high temperature. In some exceptional cases the fever was low. In one case (adult) the temperature was normal, for two days after the beginning of the disease,then a sudden high temperature. This case is now in the sixth week and still has delirium with opisthotonos and Kernig's symptom, although there is lower temperature and general improvement. In one, a fulminating case, the man went to his work in the morning complaining of headache and general muscular pains. He was seized with eclampsia while at work. I saw him that evening with his family physician. He was then comatose, temperature 106°, opisthotonos and occasional convulsions. He regained semi-consciousness next morning but died during the next night. One of my cases was semi-comatose during the whole course of the disease, which lasted four weeks. During the last two days the coma became deeper, Cheyne-Stokes respiration and death. Pain in the muscles of the back and extremities was complained of by most of the cases. There is also hyperæsthesia in all except the foudroyant cases. The patients assume, early in the disease, a peculiar attitude as they lie in bed. The patient lies on either side, not on the back; the thighs are flexed on the abdomen; and the adductors spasmodically contractured; the legs are flexed upon the thighs; the arms, flexed at the elbows, are brought over the front of the chest. The head is extended backward. This position is maintained even during delirium and semi-coma. There is much trembling, as though the patient were chilly. In the cases of the first and second class the patient has a tendency to fall into stupor except when roused. There are in the chronic cases days of improvement when the patient seems much brighter, with a lower temperature, less headache, and in every way better. Such improvement is unreliable, it is a part of the clinical history of these chronic cases, and upon it alone a favorable prognosis should not be based.

The symptoms of this disease, considered individually, are as extensive as would be expected in an acute infectious disease with a local lesion consisting of an inflammation of the brain and spinal cord and their meninges, andneuritis of cranial and spinal nerves.

The constitutional symptoms are chills, fever, slow pulse, temperature high or low, respirations, slower than would be expected with the high temperature. The temperature curve has nothing distinctive, is characterized by variations of large amplitude, and sudden in character. Symptoms due to the inflammation of the spinal cord and its meninges are stiffness of the neck and opisthotonos, pain in the spinal column, pain in the extremities, hyperæsthesia of the surface, difficulty in urination, frequent urination, constipation (may be due to the inflammation of the gastrointestinal mucous membranes), diarrhœa, incontinence of urine and fæces (paralysis of the sphincters in the last stages of the disease and during semicoma), Kernig's symptom (the most valuable and reliable physical sign that we have in cerebrospinal meningitis), eruptions on the skin of a herpetic character, affections of the joints (the joints most affected were the knees); the degree of joint trouble varies from simple pain on motion to redness, swelling and pain, and all the manifestations present in acute articular rheumatism. That these joint lesions are not toxic but trophic in character has been taught me by the occurrence in one of my cases, a child eight months old, in whom a well-marked spinal arthropathy or Charcot joint of the right elbow developed. It began with the usual appearance; but the swelling increased rapidly, the pain diminished and disappeared, soon there was subluxation of the joint surfaces upon each other with total destruction of the joint ends of the bones. This joint behaved exactly like similar joints in cases of locomotor ataxia. Diminution, but rarely absence, of patellar reflex, diminution of the skin reflex. Plantar reflex is rarely absent; Babinski reflex, which I shall speak of further on, is frequently present. Absence of patellar reflex is due to increased intraspinal pressure in these cases and acts as an indication for a repetition of lumbar puncture

The symptoms due to inflammation of the brain and medulla and their meninges and neuritis of the cranial nerves are headache, slow pulse, hydrocephalic cry, tache cêrêbrale, vertigo, convulsions, delirium, coma, coma vigil, Cheyne-Stokes respiration, photophobia, inequality, dilation or contraction of the pupils, ptosis, strabismus, optic neuritis, choked disk, atrophy of the optic nerve, iritis, iridochoroiditis, keratitis, conjunctivitis, panophthalmitis, deafness due to neuritis of the auditory nerve, paralysis of the facial and other cranial nerves, hemiplegia, monoplegia, paraplegia, and diminished or absent conjunctival reflex.

The ears and eyes are frequently infected by the presence of the organism in the nasal cavity, giving rise in the ear to otitis media and interna, and mastoid disease.

Macewen's symptom in advanced cases of coma or semi-coma due to distension of the ventricles of the brain.

Symptoms due to changes in the blood are increased leucocyte count (18,000 to 30,000 whites), a very valuable symptom which serves to differentiate these cases from typhoid fever and tuberculous meningitis. The increased leucocytosis is chiefly in the polymorphonuclear leucocytes. Eruptions of a petechial character, also skin eruptions resembling different types of erythema multiforme. (These, while not of a trophic character, are probably due to blood changes.) Finally, the most important symptom, absolutely distinctive, is the withdrawal of the cerebrospinal fluid by lumbar puncture and finding therein, microscopically, by spreads, Gram negative, extra- and intracellular diplococci, and by culture, the diplococcus intracellularis meningitidis. The cytological examination of this fluid is also important; it generally shows polynuclear leucocytes about 90 per cent. and mononuclears about 10 per cent.

Of the symptoms due to the involvement of the spinal cord, the Kernig sign has been the most useful and distinctive, both in adults and children, in the

cases I have seen. It is a decided enhancement of our objective diagnostic symptomatology. It is obtained by placing the patient upon the back, flexing the thigh at right angles with the abdomen, then extending the leg upon the thigh thus flexed. If Kernig's symptom be present the complete extension of the leg upon the thigh cannot be accomplished. The patient complains and cries out even when semi-comatose, long before the leg is brought into a line with the thigh, and the spasmodic muscular resistance cannot be overcome even by forcible efforts. As the Kernig sign diminishes, the prognosis improves. This symptom is not limited to epidemic cerebrospinal meningitis, but is present in other forms of meningitis, primary or complicating, but, as I have said, I have never seen it absent in the cases of this disease which I have seen in this epidemic. It does not disappear sometimes for weeks after recovery is complete. Bettencourt and Franca found it a very constant symptom in their large experience, it being present in over 90 per cent. of the cases. Sometimes, however, the symptom is only unilateral. It is generally unequal on the two sides. It is more marked with each exacerbation. In some fatal cases, with rapidly developing stupor, coma, slow pulse, dilated pupils and convulsions, post-mortem generally shows an acute dilatation of the ventricles. This is a fatal condition and ordinarily will give rise to the Macewen symptom, especially in young children. This symptom is founded upon the fact that the percussion note obtained by percussing the skull one or two inches behind the point of junction of the frontal, parietal, and temporal bones (a point known as the pterion) gives rise to a clearer note than is obtained over other parts of the vault of the skull, in cases in which there is increased tension (as from abscess) of the cranial contents, beneath the point percussed. The ordinary percussion note in a healthy child is dull and nearly equally distributed over the vault of the cranium. For distension of the ventricles the note behind the pterion should be compared with the note over the rest of the vault of the skull.

It is necessary in the examination that the patient sit up in bed, the head and face being free, and the skull but slightly covered with hair. Another modern symptom to which very little importance should be attached is the Babinski reflex. As you know, when the skin of the plantar surface of the foot is tickled, in some cases of meningitis, the toes are flexed and the *great toe* extended. This symptom is extremely unreliable. It occurs in some healthy children, and children suffering from other diseases. It does not occur in some well-marked cases of cerebrospinal meningitis, and is of little practical utility as a diagnostic factor.

Treatment.—From what I have said, it will readily appear that our clinical facilities for the early recognition of even mild cases of this disease are exceptionally complete at the present time. This was not true to such an extent, even ten years ago. Our therapeutic resources in the treatment of this disease have not kept pace with the advance of our knowledge of its symptomatology and pathology. Even the prophylactic treatment is uncertain, owing to our incomplete knowledge as to sources of the contagion, and the methods by which the disease is transmitted. However, the prophylactic measures indicated in my remark on the bacteriological cause of the disease seem to be necessary and simple. As far as the active therapy is concerned, there is little hope of the production of an antimeningococcus serum. It is very difficult to produce immunity with cultures of this organism, even in the smallest animals (Bonhoff, *Munchener medizinische Wochenschrift*, 1902). They die of general cachexia before the immunity has attained anything like completeness.

Bettencourt and Franca, in the Lisbon epidemic, treated their cases by injections of lysol (1–10 per cent. solutions), their death rate was only 40 to 45 per cent. In Spain, however, the death rate should be lower than in colder and moister climates, for, the climate being warm and dry, the patients are treated in the open air, or rather in rooms exposed to the open air through open windows and doors. The injections are made into the spinal canal through the trocar which is used in the lumbar puncture. The puncture is made, the fluid withdrawn, then a syringe is attached to the trocar *in situ*, and the solution is injected into the spinal canal. Dr. Morris Manges of this city has also tried this method in a number of cases, with success.

My usual method of treatment consists of repeated lumbar punctures only when, after a period of improvement, the temperature again rises, and symptoms of increased intraspinal and intracranial tension occur. Such are, total abolition of the patellar reflex, slowing of the pulse, Macewen's symptom, increase in the Kernig phenomenon, increase in the delirium and stupor. If the cerebrospinal fluid flows from the cannula in a continuous stream under tension, the withdrawal of 15 to 30 c.cm. of fluid will do much good. If it escapes drop by drop, or if it be a "dry" tap, the puncture will have no effect, from a therapeutic standpoint, upon the case. I give the sodium iodide in considerable doses: 5 to 10 grains, every 3 hours in a child over a year old; 15 to 20 grains every 3 hours in adults. In addition, also, in adults, 15 grains of mercuric ointment (ung. hydrarg.) is given by inunction into the back and neck two times daily, until the gums are red, when the inunction is stopped. In children with open fontanelles, the oleate of mercury, in proper doses is rubbed into the anterior fontanelles. In older children the ointment of mercury is rubbed into the back of the neck and spine in pieces as large as a bean, several times a day. With these methods, together with the treatment of symptomatic indications, 40 per cent. of recoveries may be expected. Ice-bags should be applied to the head, neck, and spine. As far as the temperature is concerned, when it is below 102° no treatment is required, when above 103° I use a warm bath at 80° F., in which the patient remains five minutes. The temperature of this bath is then raised to 90° F., and the patient allowed to remain five minutes more. This is the same bath that I use in the acute eruptive diseases. These baths not only reduce the temperature, but quiet the patient, who has been restless and delirious. Frequently the bath is followed by a restful sleep. Great care must be taken in the nursing and handling of the patient. The paraplegia and hemiplegia, together with the trophic disturbances of the skin, favor the occurrence of decubitus sores upon the buttocks and sides of the hips and legs, upon which the patient lies. Care and cleanliness, so well understood in these days by the physician and nurses, will obviate the occurrence of such "bed-sores." Cleanliness of the nose will prevent deeper infection through the nasal cavities. Care of an incipient conjunctivitis will prevent frequently a subsequent panophthalmitis. A daily examination of the ears should be made, for a timely paracentesis of the drum membrane in suppuration of the middle ear, may prevent a subsequent mastoid disease. Finally, and perhaps most important in the handling of this disease, is a large light room, with plenty of air space, together with frequent change of air

through proper ventilation. If the eyes are affected they should be protected from the light by means of a screen or eyeshade, and not by darkening the room. For sunlight is one of the most powerful antidotes to the bacteriological cause of this disease.

923 Madison Avenue.

REPORT OF TWO CASES OF MASTOIDITIS WITH PARALYSIS OF FACIAL NERVE; RECOVERY OF PARALYSIS FOLLOWING OPERATION.*

By SEYMOUR OPPENHEIMER, M.D.,
NEW YORK.

LARYNGOLOGIST AND OTOLOGIST, MT. SINAI HOSPITAL DISPENSARY; OTOLOGIST, GOUVERNEUR HOSPITAL; LARYNGOLOGIST, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE DISPENSARY; INSTRUCTOR IN LARYNGOLOGY, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

The coincidence of facial palsy during the course of chronic empyema of the tympanum and mastoid cells must of necessity be considered as a complication of serious importance, for while its value as a diagnostic feature of necrosis or caries may be diminished by other factors, yet it often foretells the development of either a serious cerebral affection or a sinus thrombosis. It should always be considered a grave sequelæ and recognized as a suspicious symptom of bone destruction, although ofttimes the nerve may offer considerable resistance to destructive inflammation in the vicinity of its course and may even resist inflammation after its bony covering has been destroyed. The presence of a facial palsy does not necessarily imply that there are extensive bone lesions, but it is very suggestive, and, as stated by von Troltsch, it does not of necessity imply much extension of the tympanic disease, for it may be only a slight extension in an unfortunate direction.

While paralysis of the nerve may be the result of a lesion at its origin, during its course through the temporal bone or peripherally, it is desired here to consider it only in relation to mastoiditis, and, under such circumstances as stated by Ballenger, the facial paralysis is presumptive evidence of either necrosis of the posterior-superior wall of the tympanum, whereby the nerve is exposed; or of a neuritis from inflammatory extension to the nerve through the osseous tissue surrounding it. This may be the result of caries, necrosis, cholesteatoma, the escape of pus into the facial canal or from pressure by excessive granulation tissue; the experience of Moure indicating that it is usually due to compression by fungous growths or a sequestrum, and at the same time there may also exist considerable involvement of the pneumatic spaces, especially when it occurs during the course of influenza, scarlet fever, or tuberculosis.

Anatomical peculiarities, as shown by Tomka, may favor the development of the paralysis, as dehiscences in the Fallopian canal usually located just above the oval window; variations in the course of the canal—in its width, in the thickness of its wall, or as the result of other malformations of the temporal bone. The defect in the canal, which allows of the purulent inflammation extending to the nerve, may produce a perineuritis by involving the perineurium, or it may affect the nerve itself, and thus the palsy will be the result of a definite neuritis. Even in severe palsies the mastoid operation may reveal an apparently normal canal, the affection resulting from the pressure of a small exudate as the result of inflammation in the nerve sheath, and in some cases in which the palsy has disappeared without radical treatment this exudation has subsided and been absorbed without permanent damage to the nerve. Voss, in this connection, records an instructive case in which the facial palsy had existed for some time and was cured by opening the mastoid and removing a mass of hyperæmic spongy tissue from the antrum. More frequently severe grades of facial paralysis result from the carious destruction of the facial canal, with or without complete destruction of the nerve, either as the result of cholesteatomatous formations or the extension of the destructive process to the inner ear. In such cases, besides the involvement of the mastoid, there is necrosis of the upper part of the vestibule and posterior part of the inner tympanum wall, such a case being described by Murphy with a history of ten years' standing; the wall of the canal was eroded, the facial nerve destroyed, while the horizontal semicircular canal was also involved; operation causing the disappearance of the vertigo but having no effect upon the facial paralysis, while in a case of Loubet-Barbob, the paralysis was due to necrosis of the inner tympanic wall; Stackes' operation was performed and was followed by the death of the patient, when a direct communication was found between the tympanum and cranial cavity.

Even with necrosis of the labyrinth, exfoliation of the cochlea and parts of the semicircular canals, the facial paralysis may be but temporary, but when the destruction involves the internal auditory meatus and the entire labyrinth, it is usually permanent. Although Gruber has reported two cases in which the sequestrum consisted of a complete annulus tympanicus, a part of the squamous portion and a small part of the posterior section of the pyramidal portion of the bone, with the complete disappearance in both cases of the facial paralysis which had existed during the course of the disease. Indirectly paralysis of the seventh nerve may also result from the mastoid infection extending to the cranial contents, with the involvement of the nerve in the internal auditory meatus from a meningitis or brain abscess, or again it may be affected at the further extremity of its course by the extension of the inflammation from the apex of the mastoid to the stylomastoid foramen.

The first case which I desire to report in this connection is one of chronic suppurative otitis with mastoiditis and paralysis of the left facial nerve, from apparent pressure of inflammatory exudation.

B. Y., male, age twenty-seven years, had measles at the age of six years with resulting nasopharyngeal catarrh and tendency to repeated attacks of coryza. At ten years of age he had scarlet fever, followed by suppuration of the left ear. The discharge from the ear was profuse for a year after this, but he received constant treatment, and, except for occasional discharge at infrequent intervals, it did not cause him any concern until four months ago, when following an attack of the grippe, it became unusually profuse, attended with a foul odor and with occasional shooting pains over the mastoid and temporal regions. He received treatment for this condition for three months, with marked diminution in the amount of the discharge, and with this exception suffered no annoyance. At the end of this time, on arising one morning, he saw that the lines of the left side of his face were obliterated and that his mouth was drawn toward the right. He was treated for the next two weeks in various ways for this facial palsy, without obtaining any relief, and I then saw him for the first time.

He stated that his general health was poor; he had lost weight during the last few months, and he easily tired, while his appetite amounted to very little. His pulse was 80, temperature 99.2°, bowels constipated. Eye grounds normal, no pain in head, no vertigo, and nothing presented itself in his symptoms

*Presented at the tenth annual meeting of the American Laryngological, Rhinological, and Otological Society, at Chicago, Ill., May 30, 1904.

indicating any intracranial involvement. The left side of his face was paralyzed; he could not close the eyelids on that side; he was unable to whistle, and food lodged between the cheek and gums, while he complained of the dribbling of saliva on the affected side. No paralysis of the soft palate was present, but, from the involvement of the chorda tympani nerve, taste was lost over the base of the tongue. Examination of the mastoid showed nothing abnormal, except that dull pain could be elicted on deep pressure over the antrum; the external canal was filled with offensive pus, and the membrane tympani was absent, except a rim around the annulus, while there were no evidences of the malleus, and probing indicated some necrosis of the incus. There was slight bulging of the posterior canal wall and, with the general features of the case, it seemed evident that there were considerable changes going on in the mastoid cells which had involved the facial nerve.

Previous to operation the external canal was cleansed with a 1:5000 bichloride solution, the usual preliminary antiseptic cleansing of the operative field performed, and under ether anæsthesia the mastoid was opened. Immediately under the cortex a mass of granulation tissue was encountered with a few drops of pus, while the osseus tissue presented but few necrotic areas; these were removed, the tissue appearing normal toward the tip, until the antrum was reached, when a drachm of offensive pus was encountered and the antrum and aditus were found filled with pus and poorly organized granulation tissue. This was removed with the portions of the pneumatic cells that were necrosed, and free communication established between the mastoid wound, antrum, and tympanic cavity. The remnants of the membrana tympani were then cut away, the partially necrosed incus removed, and careful search failed to reveal any further evidence of necrosis, special search being made in the region of the Fallopian canal. The parts were then irrigated with bichloride solution, the mastoid cavity was lightly packed with iodoform gauze and a large gauze dressing was applied. On the following day there was a marked alteration on the paralyzed side, the nasolabial fold was evident, and it was apparent that the condition was improving. This occurred quite rapidly, and by the end of the second week the paralysis had entirely disappeared, with the exception of the involvement of the chorda tympani nerve and slight difficulty in closing the eyelid. The mastoid wound pursued the usual course, and in four weeks the patient was discharged with the ear practically dry, the complete disappearance of the facial paralysis after six weeks.

The onset of the paralysis may be sudden and complete, as in this case, or the symptoms may develope gradually, only partial fibers of the nerve being affected as the branches supplying the nose, side of face, and angle of the mouth, or it may rarely occur only in the upper group, when the paralysis will involve the forehead and orbicularis palpebrarum muscle. When the nerve is destroyed the paralysis comes on suddenly, shows no change in its severity, and presents no facial premonitory symptoms, but when the development is more or less gradual, there usually occurs a group of prodromal manifestations that should lead one to immediately investigate the middle ear or mastoid symptoms that may be present. As the result of pressure on the nerve, which gradually develops and is attended with a diminution or increase in the amount of exudation, the paresis varies in degree from time to time, and there may be pain around the affected ear and of the corresponding side of the face, with varying degrees of tinnitus and abnormal sensations of taste. When the palsy is fully developed the saliva trickles out of the mouth, the mouth is drawn over to the unaffected side; the food collects between the cheeks and the gums; the patient is unable to whistle; liquids run from the mouth in drinking; the facial expression is lost, and there may be some disorder of taste with impaired olfaction, and the development of conjunctivitis from inability to close the eyelids.

The second case of mastoiditis with facial palsy which I desire to report here is as follows:

D. E., male, age thirty-three years. He was considered unusually robust until he was twenty-seven years of age, when he had typhoid fever, from which he did not recover for twelve weeks; and a year later he had an attack of influenza, which was followed by intense pain and suppuration of both ears. He received treatment at irregular intervals for the otorrhœa with the result that the right ear became apparently well, while the left would show a scanty discharge at times, but caused him no serious annoyance. This left-sided intermittent otorrhœa continued until one year ago, when, following exposure during a severe storm, the discharge entirely ceased, great pain was experienced over the mastoid and side of the head and continued for several days when the discharge again made its appearance, but was more profuse than before. This continued until four months previous to when I saw him, when he noticed that he had difficulty in whistling and often would have to remove particles of food which would remain between the gums and cheek on the left side. This persisted until one month later when he contracted a severe coryza and the pain in the ear increased in intensity.

I then saw him for the first time, and examination showed facial paralysis involving the lower half of the left side, the upper facial segment not being markedly involved. The upper respiratory tract was normal, except some nasal turgescence; the temperature was 100° and the pulse 90. His general condition appeared to be good and his hearing on the right ear was normal, while on the left it was but about one-half as acute. The left mastoid was slightly swollen, very painful to even moderate pressure, and the canal was filled with pus. The posterior wall was sagging inward and obstructed the view of the membrana tympani, but a large perforation could be observed filled with a mass of granulation tissue. As the facial nerve responded fairly well to electrical excitability, he was advised that radical evisceration of the mastoid was urgently demanded with a possibility of some improvement of the facial paralysis, but little hope was offered of this favorable result. He refused radical operation, as he believed with local treatment the condition would improve, but consented to any operative procedures that could be performed through the canal. During this period the tympanic cavity was cleansed daily with a formalin solution, a small piece of the necrosed malleus was removed, as was also the necrosed incus, and with snare and curette the granulation tissue was in great part removed from the tympanum. These procedures improved the drainage to some extent and greatly relieved the pain, but had no influence on the course of the disease.

Finally, as the result of persistent advice of the gravity of his condition and a marked increase of the mastoid tenderness and swelling, he consented to operation, which was performed under ether anæsthesia. After the usual aseptic preparations, a long incision was made over the mastoid curving well backward toward the tip of the process; the periosteum was detached anteriorally into the auditory

canal and the cartilaginous canal was cut across at its junction with the bony portion, while with the auricle it was reflected forward and out of the field of operation. The mastoid cortex was found to be extremely friable and at a point one-half inch anterior to the exit of the emissary vein, the bone was darkened and broke through on slight pressure. The interior of the mastoid was extensively disorganized, and great care had to be exercised in removing the necrosed bone and débris, on account of the danger of opening the sinus or perforating into the cranial cavity. The entire mastoid contents were removed with the exception of the tip, which was healthy, and then the posterior wall of the auditory canal was removed with chisel and rongeur forceps. The antrum and middle ear were cleansed of an unusual amount of granulation tissue, and on the posterior wall over the facial canal a sequestrum was dislodged and removed, which allowed the exposure of the facial nerve. The parts were then cleansed with bichloride solution, the canal wall was split into the lower aspect of the concha and held in position with iodoform gauze packing, so that full view of the large cavity could be obtained. The upper portion of the mastoid incision was then brought together with sutures and a large gauze dressing was applied over the entire ear.

On account of profuse seropurulent discharge it was necessary to change the dressings in twenty-four hours, when the facial palsy already showed some improvement. During the next two weeks the dressing had to be changed once daily on account of the profuse discharge, the temperature remaining almost constantly at 99°, and there was considerable annoyance from the excessive development of granulation tissue. During the next period of four weeks he very slowly improved in strength, the remains of the facial paralysis entirely disappeared, his temperature came to normal and the granulation tissue was controlled by tighter packing and the use of nitrate of silver. Following this there was a steady improvement in both the local and general conditions, but it was fully ten weeks before he again regained perfect health, and three months had elapsed before the mastoid wound had healed.

The technique of the operative treatment of facial paralysis the result of mastoiditis has been sufficiently outlined in the report of these two cases, but it is desired to point out a few further facts, and especially the prognosis in operation as derived from an electrical study of the nerve. When the paresis is not well developed, with the electric irritability normal, one can expect a favorable result within a short time after the pressure has been relieved, and in those cases in which partial reactions of degeneration are present, the mastoid operation should be performed with the expectation of relief some weeks after. But in the third class of cases with well-marked reactions of degeneration, the chances are against the restoration of nerve function, although the mastoid operation may be necessary, independent of the hope of removing the facial paralysis; it is always a matter of precaution therefore, to make such tests in order to obtain an intelligent opinion of the probable results of the operation as regards this distressing feature.

In extensive caries it may be necessary to curette part of the walls of the facial canal and bare the nerve, and as shown by Cozzolino, relief may be obtained by removing the inflammatory tissue from the tympanic and mastoid zones. He terms the operation radical mastoidotomy by which he frees the nerve from the diseased bone surrounding it, but in doing this one should carefully bear in mind the location of the facial canal, and while it is not in danger by removing the upper wall of the meatus, one can locate it if the field of operation be well exposed, by the bony protuberance on the inner wall of the antrum marking the site of the canal and also the external semicircular canal. It should be remembered that the upper margin of the oval window is formed by the protruding facial canal, and from this point and posterior it curves downward behind the middle of the posterior margin of the annulus, then descends in a vertical direction to its exit at the stylomastoid foramen. In some cases it is not possible to locate the nerve with any degree of accuracy, or again it may not be essential to seek it out; and then after opening the mastoid cells, the diseased bone or soft tissues should be thoroughly removed, especially in the region of the aqueductus Fallopii, with the expectation of obtaining a favorable result. Barnick reports an instructive case which he cured by cleansing the spaces of a mucopurulent fluid and leaving a permanent retro-auricular opening; Jack also cites a case in which the facial paralysis disappeared after opening the mastoid and finding a small pus cavity in the Fallopian region, while Politzer reports two cases entirely cured by surgical exposure and thorough curetting of the suppurating cavities. Finally, even in apparently unfavorable cases, the extraordinary regenerative power of the nerve should be borne in mind and an effort made to obtain relief by surgical measures as offering a possibility of success.

45 East Sixtieth Street.

REGARDING HAMLET'S SANITY.

By JOHN W. WAINWRIGHT, M.D.,
NEW YORK.

"As I, perchance, hereafter shall think meet
To put an antic disposition on." Act II, Scene I.

This utterance expressed the necessity for the exercise of a great moral struggle to put away all "trivial fond recollections"—all pleasant thoughts, to abandon all affections, under the pressure of that one absorbing commandment "remember me," which is to allow nothing in all the world to interfere with the execution of Hamlet's dread purpose. All "that youth and observation copied" is to be forgotten. The King, ever watchful, notes in Hamlet's attitude toward him, a change; the courtiers converse familiarly on his lunacy. This disguise is not accidentally chosen, but is the result of a sudden determination to guard himself while preparation is made for the execution of his revenge. As to whether he chose wisely, is a debatable point. "He," however, "casts himself like a feather upon the great wave of fate" and is in perfect harmony with his environment. His intellect revels in discoursing upon "This thing's to do." The issue will be shortly known:

"It will be short:—the interim is mine;
And a man's life's no more than to say 'One'."

Aside from the quotation at the beginning of this essay, we have throughout the play abundant evidence that his eccentric behavior was intended to obscure his plans for the execution of his revenge. No one would accuse him of madness previous to meeting his father's ghost. Note his reply to the Queen, his mother, in Act I, Scene 2:

Queen— "If it be,
Why seems it so particular with thee?"
Hamlet—"Seems, madam! nay, it is; I know not 'seems.'
'Tis not alone my inky cloak, good mother,
Nor customary suits of solemn black,
Nor windy suspiration of forc'd breath,
No, nor the fruitful river in the eye,
Nor the dejected haviour of the visage,
Together with all forms, moods, shows of grief,
That can denote me truly: These indeed seem,
For they are actions that a man might play:
But I have that within which passeth show;
These, but the trappings and the suits of woe."

One could not expect a saner speech from a philosopher, much less a young man not yet out of school.

Again, same act and scene, in reply to his mother:

Hamlet—"I shall in all my best obey you, madam."

Truly, a most courteous and affectionate reply. We now find him alone, giving way to his grief at the loss of his father and his mother's unnatural haste in marrying his father's brother within a month. This surely is sufficient cause for grief. Note that there is not a word uttered or suggested showing his disappointment in being cheated out of his rightful heritage—succeeding to the throne—cause sufficient to bring the most bitter disappointment. This hasty marriage was to forestall Hamlet's being crowned king, rightfully so. A coup must follow quickly the death of the King or the purpose of Claudius in poisoning him come to naught. This giving way to tears is for the loss of a father, for

"He was a man, take him for all in all,
I shall not look upon his like again,"

and the outrage of his father's memory by the untimely marriage of his mother.

Hamlet's amazement and profound interest at hearing that his father's ghost had been seen and his determination to "speak to it, though hell itself should gape and bid me hold my peace," clearly shows his filial love. Here is the first thought that something is wrong.

"My father's spirit in arms! all is not well;
I doubt some foul play:"

We now approach a crisis in Hamlet's life. The revelation of the ghost, its fearful accusation that murder, foul and damnable, is the cause of his father's untimely death, and that no less a person than the father's brother now the King, is the murderer and his mother an accomplice is calculated to unbalance the young man's mind. But not so with Hamlet, for immediately after the disappearance of the ghost, following the frightful detail of his father's death, the time, if at all, when we should expect to witness an evidence of the disturbance of Hamlet's intellect, we find instead the most direct and connected soliloquy spoken by Hamlet in the whole of the play:

"O all you host of heaven! O earth! what else?
And shall I couple hell?—O, fie!—Hold, my heart;—
And you, my sinews, grow not instant old,
But bear me stiffly up! Remember thee?
Ay, thou poor ghost, while memory holds a seat
In this distracted globe. Remember thee?
Yea, from the table of my memory
I'll wipe away all trivial fond records,
All saws of books, all forms, all pressures past,
That youth and observation copied there;
And thy commandment all alone shall live
Within the book and volume of my brain,
Unmix'd with baser matter:"

At this moment Horatio and his other friends call. A sudden resolution is formed not to let them know the purport of the interview with the ghost and to this end he mimics Marcellus, who calls,

"Illo, ho, ho, my lord!"

with the falconer's call to his bird

"Hillo, ho, ho, boy! come, bird, come."

For the purpose of making light of the matter and forestalling too close questioning. When pressed, Hamlet replies:

"There's ne'er a villain dwelling in all Denmark,
But he's an arrant knave."

Immediately Hamlet desires to part from his friends; to be alone with this most startling information.

"I hold it fit that we shake hands and part;
. . . . . —and, for my own part,
Look you, I'll go pray."
(To Horatio) . . . . "touching this vision here.
It is an honest ghost, that let me tell you:
For your desire to know what is between us,
O'ermaster it as you may."

Hamlet now exacts an oath that they

"Never make known what you have seen to-night.
"But come;—
Here, as before (on his sword) never, so help you mercy!
How strange or odd so'er I bear myself,
As I, perchance, hereafter shall think meet
To put an antic disposition on—
That you, at such times seeing me, never shall
With arms encumber'd thus, or thus head-shake,
Or by pronouncing of some doubtful phrase,
As 'well, we know';—or, 'We could, an if we would'
Or 'If we list to speak,'—or 'There be, an if they might';—
Or such ambiguous giving out, to note
That you know aught of me:—This not to do,
So grace and mercy at your most need help you.
Swear.
. . . . So, gentlemen,
With all my love I do commend me to you:
And what so poor a man as Hamlet is
May do, to express his love and friending to you,
God willing, shall not lack."

Again the revelation of the ghost crowds upon him and

"The time is out of joint;—O cursed spite!
That ever I was born to set it right!"

Was ever sanity more abundantly in evidence than is here manifest? This desire for secrecy and the method of securing it is not cunning or a madman's way of assuring it. It is a manly and perfectly sane procedure; showing evidence of the soundest and most profound reasoning, for if the story had been told to the friends and thus come to the knowledge of the people, there would have been a revolution with all its accompanying evils, perhaps assassination of the new king, possibly of the queen, Hamlet's mother. This must by all means be avoided for two reasons, first, to protect the mother from violence and possibly death—a most praiseworthy and dutiful thought, for aside from a filial love for her who had borne him which still possessed him, had not Hamlet's father's ghost warned him—

"But, howsoever thou pursu'st this act (revenge)
Taint not thy mind, nor let thy soul contrive
Against thy mother aught; leave her to heaven."

Then he must not be cheated of his revenge by some one other than himself executing vengeance upon the king, his father's murderer and usurper to his rightful throne. Is there not here evidence of the most profound thought, subtle and sane to a superlative degree?

Ophelia states in Act II, Scene I, in describing a visit received from Hamlet:

Ophelia—"My lord, as I was sewing in my chamber,
Lord Hamlet,—with his doublet all unbrac'd;
No hat upon his head; his stockings foul'd,
Ungarter'd, and down-gyved to his ancle;
Pale as his shirt; his knees knocking each other;
And with a look so piteous in purport,
As if he had been loosed out of hell,
To speak of horrors,—he comes before me.
Polonius— "Mad for thy love?"
Ophelia— "My lord, I do not know;
But, truly, I do fear it."
Polonius— "What said he?"
Ophelia— "He took me by the wrist, and held me hard;
Then goes he to the length of all his arm;
And, with his other hand thus, o'er his brow,
He falls to such perusal of my face,
As he would draw it. Long stay'd he so;
At last,—a little shaking of mine arm,
And thrice his head thus waving up and down,—
He rais'd a sigh so piteous and profound,
That it did seem to shatter all his bulk,
And end his being: That done, he lets me go:
And, with his head over his shoulder turn'd,
He seem'd to find his way without his eyes;
For out o' doors he went without their help,
And, to the last, bended their light on me."
Polonius—"This is the very ecstasy of love.
. . . . . .
What, have you given him any hard words of late?"
Ophelia—"No, my good lord; but, as you did command,
I did repel his letters, and denied
His access to me."
Polonius—"That hath made him mad."

Is this insanity? Can not Hamlet's dejection and melancholy be clearly attributed to disappointment at the manner of his reception by one whom he had every reason to believe reciprocated his affection? We have heard Ophelia relate to her father Polonius how:

"He hath, my lord, of late, made many tenders
Of his affection to me."

And again

"My lord, he hath importun'd me with love,
In honorable fashion."
"And hath given countenance to his speech, my lord,
With all the vows of heaven."

That Hamlet ardently and honorably loved Ophelia is without doubt. To be summarily dismissed without an explanation and at a time when he had such a heavy load to carry as revealed by the ghost, and by one whom he felt warranted in believing had cast her lot with his, had become his other self, were enough to make mad—not insanely mad but angry. He sees the whole world and everything which he counted dear slipping from beneath him. He does not demand, as is his right, an explanation from Ophelia, but humbles himself to visit her whether or no, and in her closet, whither she had at her father's command secreted herself. At sight of her, this one who has abandoned him, the only one left excepting Horatio to whom he feels a right of sympathy, he loses hope; all is for him lost, and he breaks down. Is it remarkable? Could anything else be expected of him under such trying conditions? Polonius calls him mad; he, the senile, time-serving, garrulous old fool. Follow the actions of this antiquated, meddlesome dotard and then declare him capable of passing upon Hamlet's sanity. Excepting the guilty king who has every reason to discredit Hamlet, who has with the connivance of this mischief-maker, Polonius, usurped the throne rightfully belonging to Hamlet, Polonius is the only one who pronounces our prince insane. To declare him mad would be within the limit of credulity, for that he was "distracted with trouble" we grant. It was, however, not in this sense that Polonius pronounced Hamlet mad. He makes at once to the king and exhibits his despicable nature by playing the spy upon his prince. Not content to himself spy upon Hamlet's solitude, he must command the assistance of his daughter, Hamlet's betrothed. Further, to add insult to injury, this mischief-making old dotard forces his daughter to give him Hamlet's love-letters and these he reads with contemptible comments to the king and queen.

Now follows the dialogue between Hamlet and Polonius, when the latter is treated according to his just deserts. Can anyone find aught of insanity in Hamlet's remarks during this dialogue, or in his interview with his schoolfellows Rosencrantz and Guildenstern, which quickly follows? Does he not sound the depths of these two conspirators with amazing foresight?

Again we follow him in the scene with the players; a most amazing evidence of sanity is here evident. During the recitation of the player an awful shadow is projected over him. He is again in the presence of the ghost and its frightful revelation. Quick as thought itself, he conceives a way to disclose the king. He determines to insert in the play a portion of the tragedy of his father's taking off, and to note its effect. When again alone remorse overwhelms him. He reproaches himself for his delay in wreaking his vengeance, but concludes that—

> "The spirit that I have seen
> May be the devil: and the devil hath power
> To assume a pleasing shape; yea, and, perhaps,
> Out of my weakness, and my melancholy
> (As he is very potent with such spirits),
> Abuses me to damn me: I'll have grounds
> More relative than this: The play's the thing,
> Wherein I'll catch the conscience of the king."

The king is much disturbed. He fears that Hamlet has discovered the secret of his father's death: he must discredit him, and begins at once. Of Rosencrantz, his spy, he seeks such information as may have been disclosed to him—the more the pity, as Rosencrantz is Hamlet's schoolfellow and guest.

> *King*—"And can you, by no drift of circumstance,
> Get from him, why he puts on this confusion;
> Grating so harshly all his days of quiet
> With turbulent and dangerous lunacy?"

Here we see the craft of the king. He seeks to learn of any damaging confidences with Hamlet, and at the same time casts opprobrium on him, by the assertion of lunacy. Unfortunately for the King, Hamlet has sounded the purposes of Rosencrantz and Guildenstern.

> *Queen*—"Did he receive you well?"
> *Rosencrantz*—"Most like a gentleman."

Through the meddlesome Polonius and the crafty king, Hamlet is now to be a target for their espials, and the loving and innocent Ophelia is to assist them. What baseness, what supreme cruelty. What a test for these two devoted souls. Of all the persons on earth Hamlet must find that his beloved is to be a party to his undoing; has of all the ones in whom he should trust turned false? My God, what a blow to his affections; what a test of his loyal heart; what misery to suspect his loved one of deception in the midst of such overwhelming sorrow. Here the master exhibits his marvelous skill in playing upon our weakness to emphasize and lay bare a seeming lack of devotion and fidelity to him of all others who should have been shielded and protected, even to the spilling of her heart's blood. I have always doubted that readers of Shakspere appreciated this event in shaping Hamlet's future actions, for there can be no doubt but that Hamlet realized Ophelia was a party to the conspiracy to unfold his secret.

The king would like to know that Hamlet's strange behavior is to be attributed to an excess of love for Ophelia. This would somewhat quiet his mind and lead him to abandon a fear that it was from other and more serious causes, wherein he himself might play the most important rôle.

> *Polonius*—"Ophelia, walk you here:—Gracious, so please you,
> We will bestow ourselves:—Read on this book;
> That show of such an exercise may colour
> Your loneliness. We are oft to blame in this,—
> 'Tis too much proved, that, with devotion's visage,
> And pious action, we do sugar o'er
> The devil himself.
> *King* (Aside)—"O, 'tis too true!
> How smart a lash that speech doth give my conscience!"

Here is bitter and unexpected accusation. The king's eyes are turned within. He is made to see himself as he is, not as he seems to others. Play on, thou foulest of villains, the game is young, but the bloodhounds of fate shall pull you from your ill-gotten throne, even at the sacrifice of noble and pure souls.

Now follow the noblest thoughts ever put in the minds of man, or uttered by human lips—Hamlet's Soliloquy, "To be or not to be," a speech of a few lines, couched in the purest of our beloved old Anglo-Saxon, containing not a word that cannot be properly defined by a modern ten-year-old school-boy, and yet, so fraught with awful grandeur, with philosophy so sublime, with energy so intense that we poor mortals in our pitiful limitations cannot analyze it aright, or two of us comprehend it alike for around this short speech have scholars and wise men met to fight the fiercest battles of criticism. Can any one believe that the master would put such sublime thoughts, such pregnant philosophy into the mouth of a madman? Could he have intended such an inconsistency? Never, when Hamlet is alone can there be the shadow of suspicion as to his sanity When, in the presence of those who have done him an irreparable wrong, those who are unquestionably spies, accomplices, or his enemies, he plays a part, which shall, to his mind, help him to his great revenge.

In this oliloquy we have a contradiction of what we have earlier been assured is true: Hamlet has

had ocular proof that his father s spirit revisits the earth, and converses with it, learns that—

Ghost— . . . "But that I am forbid
To tell the secrets of my prison house,
I could a tale unfold, whose lightest word
Would harrow up thy soul; freeze thy young blood;
Make thy two eyes, like stars, start from their spheres;
Thy knotted and combined locks to part,
And each particular hair to stand on end,
Like quills upon the fretful Propentine." (Porcupine.)

But here Hamlet notwithstanding this proof exclaims:

. . . "who would these fardels bear.
To grunt and sweat under a weary life;
But that the dread of something after death,
The *undiscovered country, from whose bourn*
No traveller returns, puzzles the will;
And makes us rather bear those ills we have,
Than fly to others we know not of?"

Now occurs the most despicable espionage. It is positively certain that Hamlet is secretly watched and that Ophelia is to aid the conspirators. To divert suspicion he lapses instantly from a melancholy philosophizing—albeit without a hint of madness—to that "antic disposition" which we have become acquainted with earlier in the play. The dialogue between Ophelia and himself clearly shows this. She is made to believe him mad and grieves as all true women similarly situated would. This contrived meeting is most unfortunate for her, for with this interview is the beginning of dire disaster to her, which is quick to follow.

We have a portrait of Hamlet, given by Ophelia, one eminently qualified to paint it: in painting which, however, the poor child is overwhelmed by grief in the belief that her hope for future happiness and joy is blasted. To her mind her lover, her one in all the world, is mad and therefore she is doomed.

Ophelia— . . . "O, what a noble mind is here o'erthrown!
The courtier's, soldier's, scholar's eye, tongue, sword:
The expectancy and rose of the fair state,
The glass of fashion and the mould of form,
The observ'd of all observers! quite, quite, down!
And I, of ladies most deject and wretched,
That suck'd the honey of his music vows,
Now see that noble and most sovereign reason,
Like sweet bells jangled, out of tune and harsh:
That unmatch'd form and feature of blown youth,
Blasted with ecstasy: O, woe is me!
To have seen what I have seen, see what I see!"

Poor sweetheart; the earth has slipped from under you; life for you henceforth is to be worthless. We pity, we weep for you, but our sympathy, our love, will not avail to save you; the awful shadow again approaches, which shall engulf you and put an end to your great sorrow. We forgive you as your dear one did later, for the untruth you told him:

Hamlet— . . . "Where's your father?"
Ophelia—"At home, my lord."

Oh, why did you say it? You knew it to be untrue and so did he. God forgive you. Your pure and innocent soul is not in tune with falsehood and deceit.

Hamlet—"Let the doors be shut upon him, that he may play the fool no way but in's own house."

King—"Love! his affections (affectation) do not that way tend;
Nor what he spake, though it lack'd form a little,
Was not like madness. There's something in his soul,
O'er which his melancholy sits on brood,
And, I do doubt, the hatch, and the disclose,
Will be some danger:"

The king realizes that there is some sublet method in this affectation of madness, and doubts not it will reach him if he cannot in some way dispose of Hamlet, so:

. . . "He shall with speed to England,"

Another conspiracy between the king and Polonius to betray Hamlet, this time using his own mother to aid them.

Now comes the second scene of this powerful act. (3). Read carefully Hamlet's instructions to the players and then say he is even touched with insanity. In this scene we have other evidence of Hamlet's perfect equilibrium. Here he meets with his one friend on earth whose love for, and confidence in him, gives him the only footstool upon earth; the only soul to whom he can go for sympathy and ease of mind.

Hamlet— . . . "Dost thou hear:
Since my dear soul was mistress of my choice
And could of men distinguish, her election
Hath seal'd thee for herself: for thou hast been
As one, in suffering all, that suffers nothing;
. . . . . .
Give me that man
That is not passion's slave, and I will wear him
In my heart's core, ay, in my heart of heart,
As I do thee."

What a world of affection is here disclosed. We are rejoiced to know that such confidence was not wrongfully placed; that Hamlet had this haven of rest to which he could return when storms were about to overwhelm him. We love Horatio next to Hamlet, because he was loyal, a friend "in suffering all." In the whole of Hamlet's experience, Horatio was his only confidant; the only one to whom he laid bare his bursting heart.

Hamlet (to Horatio)—"There is a play to-night before the King;
One scene of it comes near the circumstance
Which I have told thee of my father's death.
I prithee, when thou seest that act a-foot,
Even with the very comment of my soul
Observe my uncle: If his occulted guilt
Do not itself unkennel in one speech,
It is a damned ghost that we have seen;
And my imaginations are as foul
As Vulcan's stithe."

To no one but Horatio does Hamlet reveal the revelation of the ghost.

Woe to the king, for he will not escape these two observers. Hamlet, while he has the greater cause to uncover the king, will not be more acutely observant than his friend. Horatio is Hamlet's other self. The play proceeds and we find the king overwhelmed with guilt; Hamlet and Horatio exuberant. Is this cleverly laid plan the work of a madman?

Here we have the scene between Hamlet and Rosencrantz and Guildenstern, Hamlet's remarks conveying a knowledge of his companion's attempts to trap him into disclosing his thoughts.

Hamlet—"Why, look you now, how unworthy a thing you make of me. You would play upon me; you would seem to know my stops; you would pluck out the heart of my mystery; you would sound me from my lowest note to the top of my compass; and there is much music, excellent voice, in this little organ; (flute) yet cannot you make it speak. Why, do you think I am easier to be played on than a pipe? Call me what instrument you will, though you can fret me, yet you cannot play upon me."

Pretty clear evidence of a normally acting brain? This arraignment is followed by an amusing scene with Polonius wherein Hamlet plays with the old man as he will. We have something of the pathetic in this dialogue; a once virile mind trembles and totters in senile decay, his functions being dislimbed and unjointed; the plaything of a vigorous and a youthful manhood. Here, again, Hamlet feels his power and the conviction of the truth of the ghost's revelation, having but a moment before had proof of his uncle's guilt. He is elated at the success of his coup and ready for any emergency.

"'Tis now the very witching time of night (midnight)
When churchyards yawn, and hell itself breathes out
Contagion to this world: Now could I drink hot blood,
And do such bitter business as the day
Would quake to look on."

The son is, however, in evidence.

. . . "Soft; now to my mother—
O heart, lose not thy nature; let not ever
The soul of Nero enter this firm bosom:
Let me be cruel, not unnatural:
I will speak daggers to her, but use none;
My tongue and soul in this be hypocrites;
How in my words soever she be shent (put to shame or hurt),
To give them seals* never, my soul, consent!"

Rosencrantz and Guildenstern in an interview with the king show what despicable guests they are, going so far as to seek to add to the king's alarm by advising him to exile Hamlet.

Hamlet on his way to his mother's apartment whither she has summoned him at the connivance

*To make my sayings deeds.

of the king and Polonius, where the latter is secreted, hoping to learn his thoughts—O unnatural mother; will you persist in trying to confound your own flesh and blood, your only child; him whom you have cuddled to your breast; whom you have taught to speak and walk; the only soul that has deified you in calling you mother?—finds Claudius at his devotions seeking, on bended knees, forgiveness for his crime. His impulse is to then and there avenge his father's murder, but, to kill the king while in this attitude, thus praying to God, would be to send him straight to heaven. His purpose would not, therefore, be accomplished; he would not be his father's avenger, but would add to his punishment in purgatory. No, that will not do

"O, this is hire and salary, not revenge.
He took my father grossly, full of bread;
With all his crime broad blown, as flush as May;
And, how his audit stands, who knows, save heaven?
But, in our circumstance and course of thought,
'Tis heavy with him: And am I then reveng'd,
To take him in the purging of his soul,
When he is fit and season'd for his passage?
No.
Up, sword; and know thou a more horrid hent: (seizure or grasp)
When he is drunk, asleep, or in his rage;
Or in the incestuous pleasure of his bed;
At gaming, swearing; or about some act
That has no relish of salvation in't:
Then trip him, that his heels may kick at heaven;
And that his soul may be as damn'd, and black,
As hell, whereto it goes."

This might be regarded by some as a weakness but we must make allowance for the prejudice existing in those times. While we will not concede a belief that prayer, however sincere, can by any stretch of imagination waft a soul into paradise, we are not chronicling an event of the enlightened twentieth century but of the second B. C., Shakspere taking the story from Saxo Grammaticus, a Danish author who wrote in the twelfth century a story *Historia Danica*—of events occurring in the second century.

And of this interview of Hamlet with his mother—what pathos, what firmness. How he turns her eyes and thoughts to her own wickedness, and yet, withal, with such a sorrowful pleading to break from his uncle.

The "rash intruding fool" Polonius, pays the penalty for spying upon his betters. We leave him with scarcely a sigh of pity behind the arras. We have seen the last of him. If one needs must play the fool, why should we grieve that he meets with his just deserts. "Let the doors be shut upon him, that he may play the fool no way but in's own house" sounds like a prophecy. It cannot be said that he was the dupe of the king, for in all meddling in Hamlet's affairs he led. As for the necessity for such a character to round out with intense human interest a tragedy such as that of Hamlet, we will concede the point as well taken.

In this scene with his mother, critics have sought to find unanswerable proof of Hamlet's madness, but to my mind a careful reading does not bear out the opinion, for never was sanity more clearly evident. The likeness of the two brothers is most exquisitely and truthfully drawn, and with such a burst of eloquence carries conviction.

"O, Hamlet, speak no more:
Thou turn'st mine eyes into my very soul;
And there I see such black and grained spots,
As will not leave their tinct."

While in the heat of disclosing his mother's sins the ghost reappears. This to my mind comes as near to dethroning Hamlet's reason as did the ghost revelations. He appeals again to the protection of heaven. The queen who does not see the apparition is amazed that Hamlet should.

. . . "bend your eye on vacancy,
And with the incorporal air do hold discourse?"
Hamlet— "Do you see nothing there?
. . . . . .
Nor did you nothing hear?"

The appearance of the ghost has upset our Hamlet and is it any wonder? Stop for a moment and think what this second visit of his father's ghost must have meant to him.

"Do you not come your tardy son to chide,
That, lapsed in time and passion, lets go by
The important acting of your dread command?"

Loving that father as he did, vowing speedy vengeance upon his slayer, to be thus recalled—"To whet thy almost blunted purpose," is equivalent to a reproach. The spirit which impelled him to exclaim,

"Haste me to know it; that I, with wings as swift
As meditation, or the thoughts of love,
May sweep to my revenge,"

has become dulled. He is calculating upon what course to pursue while he has lost none of his desire to obey the dread command, but considers it more to his purpose for a fuller revenge to proceed with such caution as will the more surely overwhelm with deep damnation his villainous uncle.

The queen does not perceive the ghost and is "amazed at this bodiless creation ecstacy." Now note Hamlet's reply:

"Ecstasy!
My pulse, as yours, doth temperately keep time,
And makes as healthful music: It is not madness
That I have utter'd: bring me to the test,
And I the matter will re-word, which madness
Would gambol from. Mother, for the love of grace,
Lay not that flattering unction to your soul,
That not your trespass, but my madness, speaks:
It will but skin and film the ulcerous place;
Whiles rank corruption, mining all within,
Infects unseen. Confess yourself to heaven;
Repent what's past; *avoid what is to come;*
And do not spread the compost o'er the weeds,
To make them rank."
. . . . "So again, good-night!
I must be cruel, only to be kind:
Thus bad begins, and worse remains behind."

Hamlet must to England. All is arranged. His schoolfellows Rosencrantz and Guildenstern have received instructions to accompany him, to act in fact as his jailers. But, as subsequent events show, they are dealing with one who knows their purpose and who outwits them.

I am not quite sure of the queen's motive in describing Hamlet as mad when she informs the king that he had slain Polonius. Her interview with him, a most amazing and eventful one, first discloses to her, as it were, a mirror and compels her to see herself reflected therein; brings the blush of shame to her face and causes her to, for the first time at least, repent of the part she has played before and since the death of her first king. She is overwhelmed at his arraignment of her and his knowledge of events connected with the king's untimely death. His fierce outburst of indignation startles and frightens her. She knows not what will follow, but is apprehensive of some fearful tragedy. Then Hamlet's sudden violence in slaying, as he supposed, the king—"I took thee for thy better"—and his indifference at Polonius' death has quite overcome her with fear for what may at any moment occur when Hamlet meets with Claudius. Hamlet's perturbation when the ghost appears—invisible to her—and his conversation with space is so grewsome that taking all into account she might naturally conlude Hamlet insane and capable of visiting most severe and fatal punishment upon her present king, or even upon herself. Either from this kind of reasoning, or to protect him from the vengeance of the king she pronounces him mad. (Insane.)

As for the king, he is glad of some excuse to banish Hamlet, for "He's loved of the distracted multitude,"—to get him to England, whither secretly he sends a request or rather command to have him put to death. His subsequent action proves the king a hypocrite as well as a villain.

"We must, with all our majesty and skill,
Both countenance and excuse."

Again his fellow schoolmates are made by Hamlet to understand his estimate of their friendship.

Rosencrantz—"Take you me for a sponge, my lord?"
Hamlet—"Ay, sir: that soaks up the king's countenance, his rewards, his authorities."

Hamlet's replies to the king, who is desirous of knowing the whereabouts of Polonius' body, are purposely given to show his contempt of the questioner. After the interview with Fortinbras' Captain, Hamlet charges himself with cowardice:

. . . . "I do not know
Why yet I live to say *This thing's to do:*
Sith I have cause, and will, and strength, and means,
To do't."

Read this soliloquy and be convinced that he who uttered it was truly a profound thinker, reasoner, and philosopher. One must have absolute control of his reasoning to thus discourse. A new resolve possesses him; he will henceforth

. . . . "from this time forth,
My thoughts be bloody, or be nothing worth!"

We have reached the crisis in Ophelia's life. Through the loss of lover as well as of father her mind topples and she becomes an object of our most profound sympathy and pity. The shadow again throws its colossal figure over the doomed. The end approaches swiftly. Innocent and guilty alike must go down. Fate has sealed their end, and such an end. The supreme tragedy of the world, of all ages and of all time, is approaching its end. We shudder and hold our breath at the tremendous climax that is foreshadowed. But we can only sit fast and wait.

The fiery Laertes returns from France, finds his father slain, his sister mad. He seeks the guilty one upon whom he may wreak his vengeance, suspects the king.

Laertes—"Where is my father?"
King—"Dead."
Queen—"But not by him."

While quite prepared to hear the queen accuse her son, we are spared.

I do not assert that the queen has plotted the destruction of Hamlet, but she is surely aware of plots and counterplots against him. Here the master is considerate of our feelings to the extent that he will not degrade a mother and exhibit her as one with a disposition to openly plot her son's death. She is at times, however, perilously near mortally offending us. Shakspere deserves our gratitude in not making prominent her real feelings and desires. There is quite enough in this story to harrow our feelings; of disappointment in humanity and regret that such treachery could be, nay was, without adding the horrors of witnessing a mother's inhumanity to her own child. Herein we must admire him above all other dramatists, for while he never spares the male villain, he deals generously with women.

Now comes the dialogue between the king and Laertes to sate his vengeance on Hamlet. They hatch as foul and villainous a plot as could be conceived. Here is rank treachery and an inhuman scheme to take Hamlet's life by the foulest and most contemptible means. One is actuated by revenge, the other by fear. Fair and honorable means are not to be relied on. Hamlet is to be poisoned by one or the other.

We are surprised and disgusted with Laertes, for heretofore he has been an honorable and high-minded young man. But his cowardice is here quite apparent. He is not to trust to his skill as a renowned swordsman, said to be the best of many countries, but will anoint his rapier with a deadly poison. That a gentleman should possess such a powerful, death-dealing substance is to be marveled at, but that he proposes to and does use it in what Hamlet, his former friend, is led to believe a friendly bout, is most despicable. The king maintains his reputation as a murderous villain, and will make himself more secure on the throne by Hamlet's death through—all else failing—a poison to be given him in a goblet of wine which he himself will offer while apparently hospitably drinking to his health and success.

Ophelia is drowned; a sad ending to a troubled and sorrowful life. Hamlet unexpectedly discloses himself at the burial and here becomes for the third time—the first being at the interview with the ghost, the second in the interview with the queen—perilously near losing his reason. He violently assails Laertes and upbraids him with a too-evident desire to show the spectators the depth of his affection for his sister—

"But, sure, the bravery of his grief did put me
Into a towering passion."

But this dispute is for the time smoothed over and Hamlet recovers his self control and discourses with Horatio.

What marvelous learning is shown in the scene with the grave diggers and what mental resources in the description of his exchanging the letters given Rosencrantz and Guildenstern for those composed by himself? The plot of the king does not carry, for:

"There's a divinity that shapes our ends,
Rough-hew them how we will."

The time had not yet come; there is yet much for our Hamlet to do. If he has ever had a doubt of the king's purposes concerning himself, these doubts are surely removed in learning that the king had in his commission given command to have him beheaded immediately upon his arrival in England. Again his purpose to be avenged on Claudius is strengthened. He will about it at once, but the issue of the business:

Hamlet—"It will be short: the interim is mine;
And a man's life's no more than to say, one."

He regrets his quarrel with Laertes. His finely wrought nature grieves at having given offence to any one. He feels for and sorrows with Laertes in his loss of father and sister. Here is evidence of courtesy, princely dignity, and regrets that in a moment of great excitement and provocation—for did not his love for Ophelia "outweigh that of forty thousand brothers?"—he should have lost his control of self.

The hellish plot against our Hamlet grows. The meshes which are to encompass him are woven more securely and immediately about him. There is to be no failure. Hamlet is doomed. He is to become a victim, and perish in his own home and at the hands of his friends. But have a care, Claudius. Your star is declining. You have loosed the bonds of affection and friendship and girded yourself with those of treachery and villainy. But he who would betray his kith and kin must expect to be rewarded in kind.

The king's messenger comes to arrange a friendly (*sic*) bout between Hamlet and Laertes. Hamlet casts himself into the business all unconscious of treachery; accepts the conditions, time and place, but to Horatio he gives voice to a foreboding that all is not right: "But thou would'st not think, how ill all's here about my heart:"

Horatio—"If your mind dislike anything, obey: I will forestall their repair hither, and say, you are not fit."
Hamlet—"Not a whit, we defy augury; there's a special providence in the fall of a sparrow. If it be now, 'tis not to come; if it be not to come, it will be now; if it be not now, yet it will come: the readiness is all: Since no man has aught of what he leaves, what is't to leave betimes?"

The sincere and manly speech of Hamlet to Laertes again stamps his nobility of character and gentleness of disposition. In this speech Hamlet charges himself with distraction. What he had done was not Hamlet's doing, but is chargeable to

madness, *i.e.* anger, the victim of a powerful emotion, and not insanity.

The climax in this all-absorbing tragedy has arrived. The colossal shadow has engulfed our hero, our friend. The long sought and looked for event has unexpectedly arrived. Hamlet's father's death is at last to be avenged. Guilty and innocent are alike to suffer. The reckoning has come. The guilty conspirators are to suffer through their own treachery and villainy. The irrevocable law of compensation is to even up the accounts. In the taking off of the king and queen and Laertes we experience scarcely a regret. But in the loss of our Hamlet we sincerely grieve. What an untimely and horrible ending for our prince. With Horatio we exclaim:

"Now cracks a noble heart."

Hamlet—"You that look pale and tremble at this chance,
That are but mutes or audience to this act,
Had I but time (as this fell sergeant death,
Is strict in his arrest)—O, I could tell you—
But let it be: Horatio, I am dead;
Thou livest; report me and my cause aright
To the unsatisfied."

Horatio— "Never believe it
I am more an antique Roman than a Dane:
Here's yet some liquor left."

Hamlet—"O, good Horatio, what a wounded name,
Things standing thus unknown, shall live behind me!
If thou did'st ever hold me in thy heart,
Absent thee from felicity a while,
And in this harsh world draw thy breath in pain,
To tell my story."
"O, I die, Horatio;
. . . . . .
But I do prophecy the election lights
On Fortinbras; he has my dying voice;
So tell him, with the occurrents, more and less,
Which have solicited.—The rest is silence."

Horatio— . . . . . .
"You from the Polack wars, and you from England
Are here arrived, give order, that these bodies
High on a stage be placed to the view;
And let me speak, to the yet unknowing world
How these things came about: So shall you hear
Of carnal, bloody, and unnatural acts;
Of accidental judgments, casual slaughters;
Of deaths put on by cunning, and forc'd cause:
And, in this upshot, purposes mistook
Fall'n on the inventors' heads: all this can I
Truly deliver."

There is no time when Hamlet's reason is wholly shaken. In the interview with the ghost, as elsewhere stated, it almost forsakes him, but this is quickly followed by an intense and marvelous self-poise. If confirmation were wanted of his firm grasp of self, or that he had assumed madness, thinking that it would help him in his pursuit of revenge, that he himself fully realized that his purposes and conduct were wrongfully understood, it will be found in the last and most pitiful scene when mortally wounded through the treachery of those he trusted, he commands Horatio—as just quoted:

. . . . "report me and my cause aright
To the unsatisfied."

This only friend in all the world has known him as he was, others only as he seemed. To regard Hamlet as insane, is, to my mind, totally unwarranted from a careful reading of the play, and is mainly due to the fact that we do not understand his motives, his character, and his environments. To so regard him is to misinterpret the master's intent.

The above quotations are taken from the unexpurgated edition of Shakspere, edited by Charles Knight, and published by Virtue & Company, London. They will differ materially from the more modern editions and stage renditions, in that they are an exact reproduction of the first folio edition of Hamlet printed in 1603. The quarto edition, which is the one in more general use, gives numerous contrary readings.

For obvious reasons much of the original text is regarded as unsuited for the parlor or schoolroom.

ILLUMINATING GAS POISONING; ITS RATIONAL TREATMENT.

By ERNEST VALENTINE HUBBARD, A.M., M.D.,
ASSISTANT ATTENDING PHYSICIAN OUT-PATIENT DEPARTMENT, ROOSEVELT HOSPITAL, NEW YORK.

Through the courtesy of Dr. Charles A. Manson of this city, I was recently called to see a patient suffering with illuminating gas poisoning. She was seventy-five years old, and had enjoyed continuous good health up to the time of her accident. Retiring, as usual, she failed to appear for breakfast, and the door being broken in, the patient was found comatose. It is significant, that a canary bird lay dead near at hand from asphyxiation. On examination, some three hours later, I found the coma persisting. There were Cheyne-Stokes respiration, air hunger and cyanosis. Pulse rate 120, heart action irregular in force and frequency. Pupils mid-wide, equal, loss of reaction to light. Marked rigidity throughout. The median cephalic vein was hurriedly opened, and nearly a liter of blood removed, which was notably dark and viscid. Following this procedure, an attempt was made to introduce a normal saline solution into the same vein; this failed, however, as there was at hand only a sharp-pointed, hollow needle, therefore abdominal hypodermoclysis was substituted. The pulse, which had become thready, rapid, and barely perceptible, began to improve within a few minutes. The subcutaneous injection was continued until 1,200 c.c. had been given. After another hour the patient showed the first signs of returning consciousness; by nightfall she had quite recovered.

In a woman of the age of this patient (seventy-five), so gravely poisoned, we expected the subsequent advent of multiple neuritis, and very possibly, some of those obscure mental and nervous symptoms, that follow in the wake of such poisoning. Nothing of the kind, however, has occurred, several weeks having uneventfully passed, and the patient continues in good condition, regaining rapidly her strength.

It has seemed advisable to report the above case, in view of the strong prejudice existing among physicians against venesection and saline solution in coal-gas poisoning. When *laissez-faire* would have caused this woman's death, a prompt removal of the offending poison from the blood, and with it a certain proportion of the destroyed red blood cells, gave her brain centers an opportunity to recover.

The saline infusion acts simply to dilute the remaining poison, and furnish the heart with fluid to continue its work, until the blood-making organs can furnish a new supply. The secret of success lies first in early venesection, every hour passing, after such a patient is found, brings death so much closer. I have seen such patients recover when exposed to the gas for six or even eight hours, and then another twelve hours passing before operation. This, however, is the exception, not the rule.

The danger of peripheral neuritis and mental symptoms is enhanced directly in proportion to the length of time elapsing before operation. I am inclined to think that the prolongation of this period is relatively of graver import in prognosis than is the difference of an hour or two in the duration of the gas-inhalation.

During this second period before operation, the coma deepens, the pulse grows progressively more rapid, the rigidity increases, all symptoms grow worse. I recall several cases, in which, immediately after discovery, the patients could be more or less roused, later lapsing into profound coma, as the poisonous carbon monoxide progressed in its de-

struction of blood cells. Therefore, early operation is indicated.

The question is often asked as to how much blood should be allowed to escape. As to this, there is no definite rule, the amount must be determined by the condition of the pulse. I think we more often remove too little than too much. When the pulse becomes *feeble* it is time to stop. The change in rate is of no great value as an indicator, for in some instances the pulse is more rapid as the bleeding progresses, and in others less so (in the above case the pulse rate dropped to 105 in the first few minutes after the vein was opened). Again, the amount of saline infusion is to be employed dependent on the pulse-character. When the radial artery at the wrist gives a full, steady pulse beat, sufficient infusion has been used.

As to the advisability of a second blood-letting, some hours should be allowed to elapse before considering this. Often, for a time, following venesection, there is improvement only in the pulse and color, respiration remaining impaired, and the coma persisting. If there be any signs of returning consciousness, it is best to wait before beginning a second operation. If four or five hours have passed, with no evidences of awakening, a second venesection may be indicated, more caution being required in judging of the amount of blood to be drawn.

In conclusion, it may be said that the existing prejudice among physicians against this method of treatment is, I believe, unfounded. If the venesection is done with care, and good judgment used, following the above rules, as to the amount of blood removed (for here, as I have intimated, lies the secret of success), no harm can be done the patient, and probably lasting good. In a word, then, the cardinal points are early operation and the removal of a sufficient amount of blood. Textbook accounts of the treatment of this all-too-common accident are so meager and unsatisfactory, that I have given the above in considerable detail.

138 West Seventy-fourth Street.

Some Factors in the Etiology of Pneumonia.—J. M. French calls attention to the increasing mortality from pneumonia. This is greatest at the two extremes of life, and least between the ages of three and twenty years. It is doubtless true that the number of cases is less in females than in males, but that the mortality in proportion to the number of cases is greater. The Jews show a greater than average vitality and resistance to this disease. Statistics show a preponderance of mortality among the city residents over the inhabitants of rural districts. The two extremes of the social scale are each more favorable to the disease than the middle walks of life. Osler states that pneumonia is more prevalent in the Southern than in the Northern States. From December to May, it has been computed that many more die from pneumonia than from June to November. Persons insufficiently protected and without an abounding vitality and power of resistance are subject to an increased mortality from pneumonia. Debilitating causes of every kind predispose to the disease, alcoholism being the most common and potent of these. A previous attack of the disease is also an important factor. Some authorities believe that traumatism is a predisposing factor. Pneumonia is a specific infectious disease. But two or three elements are generally necessary before one succumbs to the disease—a weakened condition of the system, exposure to cold and damp and sudden temperature changes, and the presence of the specific germ. One theory of the recently increased prevalence of the disease is in accordance with the belief that all infectious diseases pass through periods of rise, increase, greatest virulence, and gradual decline.—*Medicine*

The Transmission of the Immune Hæmolysins from the Fœtus to the Mother.—Kreidl and Mandl present the results of their experiments carried out in goats, for the purpose of ascertaining the behavior of the blood serum in a pregnant individual, when the fœtus is injected with blood, for which the maternal blood serum does not normally contain any hæmolysin. In goats it was found that in the majority of instances in which bullock's blood was injected into the fœtus, a specific hæmolysin could be later demonstrated in the maternal blood. This specific hæmolytic property showed a distinct increase in power during further observations. The latter also seem to show that the organism during the later stages of intrauterine existence, possesses the ability of developing specific hæmolysins. Immune bodies, therefore, are transmitted from the fœtus to the mother.—*Wiener klinische Wochenschrift.*

A Symptom Complex Simulating a Perforation Peritonitis.—E. Rochard reports a case in which a patient was suddenly seized with severe abdominal pains, which became localized in the right side and were accompanied by continuous vomiting. The patient was convalescing from typhoid fever, and a diagnosis of intestinal perforation was made, as the other typical signs were also present. A laparotomy disclosed nothing abnormal in any of the abdominal organs except a vascular area of redness in the transverse colon. The latter was also filled with fecal material, which was pressed down into the rectum. The patient made an uninterrupted recovery. The author finds two similar cases reported in the literature. He believes that this train of symptoms may be ascribed to the localized congestion acting on an extremely sensitive peritoneum, and concludes that there is no way of distinguishing the two conditions. As perforation is so frequent, it is better to do an exploratory laparotomy in every doubtful case rather than to take any chances.—*Wiener medizinische Blätter.*

Status Lymphaticus, with Report of Cases.—Robert A. Biechele declares that of the morbid findings in this affection, none is more constant than that of the enlarged thymus gland, and in exceptional cases this may be the only manifestation of morbidity. In appearance, the pathological specimen is not unlike that of the normal gland, unless cystic degeneration, a very unusual condition, has occurred. Microscopically, the only observable feature is the degeneration occurring in the corpuscles of Hassal. The weight varies from little above normal to 140 or 150 grams. Associated with the enlarged thymus there is a general hyperplasia, involving part or all of the lymphatic structures and presenting various degrees of hypertrophy. The lymph nodes of the neck, axilla, groin, and popliteal space may be enlarged, as may also the tonsils. The mesenteric and retroperitoneal modes share in the hyperplasia and may become very large. Microscopically, there may be seen in them a vast increase in the number of germinal centers, the cells of which present a tendency to degeneration. The intestinal follicles are all prominent. The writer shows a cut of a specimen in which Peyer's patches are markedly elevated, and in the ileocæcal region distinctly aggregated. Under the microscope the lymphoid elements show extensive hyperplasia and a tendency to destruction of the mucosa by self-digestion. Generally the spleen is enlarged. The Malpighian bodies are seen on section to be remarkably prominent. The kidneys often show cloudy swelling. The liver may show evidence of fatty degeneration. The skin is peculiarly pallid, a very distinctive feature, as is also the usual underlying cushion of fat. Hypoplasia of the heart and blood-vessels is often seen, particularly is this true of the aorta and its branches. The cause of death has not yet been learned. The writer cites several cases, and speaks of the thymic asthma as being most important in a diagnostic point. Of equal importance he quotes the convulsive seizures. In all of the three cases reported, epileptiform convulsions were present.—*Archives of Pediatrics.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51, FIFTH AVENUE.

New York, Sept. 10, 1904.

DIAGNOSIS OF APPENDICITIS.

Dr. W. BLAIR BELL, in the *Liverpool Medico-Chirurgical Journal*, June, 1904, considered certain points in the diagnosis of the various stages of appendicitis.

According to the writer, appendicular colic may be distinguished from renal or biliary colic—(*a*) by the history; (*b*) by the character of the pain, which, though sharp, is nothing like so severe as that produced by renal and biliary colic; (*c*) by the ability of the patient in appendicular colic to localize the seat of pain in the majority of instances.

From intestinal colic it may be distinguished by the continuous nature of the pain, by the fixed and recognizable position of it, and by the fact that pressure on the abdomen which relieves intestinal colic aggravates that of appendicular origin. Appendicular colic must, too, be distinguished from colic of uterine origin, which is sometimes seen in girls who have not menstruated regularly.

Dr. Bell points out that the following conditions are apt to lead to a wrong diagnosis: Intussusception; ulceration and stenosis at the site of Meckel's diverticulum; tuberculosis of the ileum with abscess; pyosalpiux; tubal pregnancy; perforated gastric ulcer; abscess of the liver, and cases in which no diagnosis is considered possible. Referring to the cutaneous hyperæsthesia said to be coincidental with the area of skin supplied by the eleventh dorsal nerve, and stated by many to be a constant symptom of acute appendicitis before the occurrence of perforation or gangrene, the writer is of the opinion, judging from his own observations, that this is not by any means a constant symptom nor confined to the area supplied by the eleventh dorsal nerve.

With regard to the localization of the lesion when acute perforation has taken place, Dr. Bell states that this may be determined by the fact that during the process of anæsthetization the muscle area over the affected region remains rigid after the rest of the abdominal wall has relaxed.

Respecting the indications pointing to infection of the appendix in chronic appendicitis, the writer gives the following: (1) Should the history of the case be that which generally manifests itself in chronic appendicitis, but accompanied by exacerbations of the pain at intervals, which may be attacks of true appendicular colic, or attacks of a more obscure nature, accompanied or not by a raised temperature or vomiting—the pain being in the appendix region or elsewhere, of a more fixed nature—then it is probable that the case will not recover until the appendix has been removed. (2) Any case of the type indicated which resists treatment by aperients; antiseptics, such as salol; restricted and selected diet; lavage, and above all, any case aggravated instead of improved by a course of daily abdominal massage, has some irritant cause as its basis, and that cause is an appendix in a state of chronic inflammation. (3) The following signs are also useful in determining appendix infection: (*a*) General hyperæsthesia of the abdomen. (*b*) What Dr. Bell calls the "reflex pain sign." If the patient complains of pain in the neighborhood of the umbilicus or hypogastrium, it may be found that pressure by palpation in these positions does not increase the pain, but that pressure over the appendix will do so, even though not producing pain in the region of that organ itself.

Dr. Bell believes that a primary so-called "typhlitis" can exist, although of a slow and chronic nature, but that it cannot exist long without infection of the appendix. With this belief Deaver entirely disagrees, and thinks that "the idea of a primary typhlitis is being dissipated." Dr. Bell, while allowing that all must agree with Deaver that appendicitis is the primary condition in practically all the primarily acute and acute-chronic cases, yet is of the opinion that in the swing of the pendulum we have passed over the intermediate condition—a condition of chronic typhlitis cum appendicitis.

The difficulties in the way of correctly diagnosing appendicitis are various and manifold, at times, of course, impossible. In the earlier stages when catarrhal irritation and colic are the leading symptoms, an accurate diagnosis in the majority of cases is out of the question.

The acute forms, manifesting themselves as peritonitis, can always receive appropriate treatment, although even in such cases it is not always possible to assert that the appendix is at fault until operation has been performed.

THE PROPHYLAXIS OF VENEREAL DISEASES.

UNDER this title Assistant Surgeon-General Valery Havard contributes an article to the *Journal of the Association of Military Surgeons* for July, embodying his conclusions from a special study in connection with several official services relating to the matter. On this subject statistics are notoriously unreliable, the least so being those of the various armies and navies. They are not perfect, but they are better than any other. As a measure of the unreliability of statistics from civil life, we recall the fact that the committee appointed by the Medical Society of the County of New York found that in a New York public hospital it was "ordained that these diseases appear not under their true names, but disguised under a variety of aliases which do not betray their venereal origin."

Beginning with the armies we find that in those of Germany, Belgium, and France, the rate of late years has been diminishing. The statistics of the English army and those of the Italian show conclusively the effects of sanitary regulation of prostitution. Taking the armies, in Great Britain, during the period 1870-82, prostitution in certain garrison towns was under sanitary control, while in others it was entirely unrestricted. The result was that in

the towns under control the ratio of admissions was only 50 per 1,000 men, while in the unrestricted it was 118. In 1883 the compulsory examination of prostitutes having ceased in all Great Britain, the rate in the towns previously under control rose to 110, and to 138 in 1884. The effect of reglementation was strikingly shown at Cape Town (South Africa) as well as in India. At Cape Town the yearly average for the period 1884-88, before prostitution was regulated, was 674 per 1,000, while after the enforcement of compulsory examination (in 1889) the ratio fell to 349 for the period 1889-97. In India, when all reglementation was abolished, in 1888, a frightful increase took place at once; in 1895, out of 36,681 admissions to hospitals, 22,702 were for syphilis. In 1897 certain protective measures, such as the removal of prostitutes beyond military boundaries and the examination of those voluntarily submitting, having been adopted, there was at once a reduction in the rate of admissions, the figures for 1899 being 313.5, . . . the lowest known since 1890." In the United States the rate of admissions during the normal peaceful decade 1889-1898 was 71.45 per 1,000. With the reorganization and increase of the army made necessary by the Spanish War, the rate rose steadily and, for the year ending June 30, 1900, was (for troops in the United States) 127.35. It has continued to increase: thus, for the year ending June 30, 1901, it was 155.39, and for the year 1902, according to the last report of the Surgeon-General, it was 160.94.

For civil life we are dependent on the educated guesses of specialists. These seem to indicate a greater prevalence than among soldiers. Thus, for Berlin Blaschke suggests a syphilis rate of 10 per cent. of the males, and Erbs one of 12.2 per cent., which would correspond to about 400-500 per 1,000 for all venereal diseases. The proportion of syphilitics in Paris is placed at 13-16 per cent. of the adult male population, but Fournier's estimate corresponded to 25 per cent. of this population. The Committee of the Medical Society of the County of New York believed, on fair data, that 225,000 cases of venereal diseases were treated in Greater New York in 1900, or 64 per 1,000. Sturgis had previously estimated the proportion at more than three times this figure. If we congratulate ourselves prematurely on an increase in our urban virtue, we are confronted by the fact that more than half the replies to the question whether venereal diseases are on the increase in New York, were affirmative, and by the further fact that our army stands highest in the world for these diseases. It is much more probable then that the statistics are at fault, and Havard sees reasons for believing that venereal diseases are at least as common in civil life as in military.

Turning now to prophylaxis, all attempts at suppression of prostitution have uniformly failed. The best results are obtained by police and sanitary control of it. That such control is useful has been demonstrated by experience. The fact that in some places and at times reglementation has not been efficient, is an argument for improving the character of the supervision, not for doing away with it. In Havana the existing Spanish system was reformed and perfected early in the American occupation. The result was that a city, proverbially addicted to pleasure, has probably a smaller rate of venereal diseases than any other city of its size. Thus, in 1900, the number of women registered and examined was 852, of whom less than one-tenth were found diseased. Of the 8,000 members (all males) of the Covadonga Mutual Association, only 213 came under treatment for venereal diseases, or 2.66 per cent., although such treatment was free to all members.

In America, however, public opinion, at least in its present state, will not tolerate compulsory official supervision. No such law could be passed, or if passed it would probably be impossible of enforcement. Under these circumstances the best that can be done is to require a report of venereal, the same as of other infectious diseases. Also there should be established free dispensaries and hospitals for their treatment. At present, accommodations for such cases are sadly lacking, especially in the first (most infective) stage.

Upon report, boards of health should be empowered to inspect and to compel any one found diseased to submit to treatment in hospital or by some licensed physician. Also they should have power to segregate for treatment any diseased prostitute.

Instruction as to the consequences of venereal diseases should be given in our colleges by competent physicians to youths over eighteen years of age, and a plain talk could be given by the regimental surgeon to the soldiers. Although it is a question not only of averting punishment from the guilty, but also in many cases of protecting an innocent third party, Col. Havard expresses himself as opposed to the teaching of methods of preventing infection after impure intercourse. This is comparable to the state of mind of the trustees of a certain dispensary in which the establishment of a genito-urinary clinic was not permitted because "the trustees will not foster vice by curing the diseases produced by ungodly conduct." Dr. Havard insists upon the importance of moral education, and in this all will be agreed with him. As practical physicians and sanitarians, however, we must recognize the existence of an age-long evil, and even if fostering the somewhat Utopian idea of eventually eradicating it, we must not let such a dream thwart our efforts to reduce to a minimum the direful consequences to the human race of the evil as it exists.

American Nurses in Japan.

It appears that American nurses are not too welcome in Japan. Although perhaps the polite Jap would hardly apply to them the term that Sir Frederick Treves used in referring to the lady nurses in South Africa when he said that the two plagues in that country were women and flies. Yet his thoughts in reference to lady nurses probably would run in a similar groove. Mr. Curtis, who is writing special letters from the Far East to *The Globe*, says that "of all the difficulties the Japanese government has been compelled to contend with since the beginning of the war the most perplexing were the newspaper men and the American nurses. Neither were wanted, and both have been inexpressible nuisances. The nurses have been splendidly treated, they have been almost killed by politeness and buried under gifts and have been sent to the other end of Japan, where they are supposed to be nursing sick soldiers and prisoners of war, but at the same time they have been a source of the greatest annoyance and anxiety to the Government. The medical officers of the army regard them as an incu-

bus. While grateful for the self-sacrifice shown in traveling so many thousand miles to nurse wounded and sick Japanese soldiers and sailors, the medical department has been frightfully embarrassed by these attentions. The nurses cannot speak or understand Japanese nor any other language but English. Consequently, few of the army surgeons or soldiers can converse with them. Obviously this ignorance of the language is an almost complete bar to the usefulness of the nurses, and nullifies their good intentions. But further than this, the American nurses cannot eat Japanese food or live in Japanese style. Therefore the medical department has had to spend a great deal of money and take a lot of trouble to remodel one of the houses at the Hiroshima Hospital in modern style and employ European cooks to make their unwelcome guests comfortable. In fact, they have been in the nature of a white elephant."

Finally, the nurses were not needed, as Japan possesses an army medical organization equaled by no nation, and thus, as Mr. Curtis puts it, "the services of the lovely American nurses were not needed, but as a social event, and as a manifestation of the sympathy and kindly sentiment of the American women for Japan, their visit has been an eminent success."

The above account gives rise to some somewhat sombre reflections. Why, for instance, did not the nurses and those responsible for their despatch, acquaint themselves with the conditions in Japan before embarking upon the enterprise. Doubtless most of them were mainly actuated by dictates of humanity and philanthropy, but although it may seem cruel to say it, these were not the sole motives which swayed them. Curiosity, a love of change, and the gaining of a certain amount of glory were also propelling influences. On one thing, however, we shall have reason to congratulate ourselves, we shall obtain a better knowledge of Japanese social life and habits and of Japanese medical methods, for among so many women it will be strange indeed, if there are none who are able and willing to wield a pen.

Social Causes of Alcoholism.

A great wave of sentiment against the abuse of alcohol is sweeping over the civilized countries of the world at the present time. The fact is freely recognized that intoxicating beverages are responsible for not only an immense amount of misery, poverty and vice, but for many of the diseases which affect body and mind. A determined effort is being put forth by philanthropists and by scientific men to check the curse of drink as far as is possible.

Dr. W. C. Sullivan, at the recent meeting of the Medico-Psychological Association of Great Britain and Ireland, pointed out that the bulk of the social evil wrought by intemperance was due to chronic alcoholic poisoning, not to simple drunkenness. Thus suicide, crime, insanity, and racial deterioration—in so far as they were caused by drink—depended on chronic alcoholism. But the sort of drinking which led to casual drunkenness might be entirely different from that which led to chronic intoxication. Drunkenness in its simple form was the result mainly of convivial drinking, of the drinking that went with conditions of relative luxury; it was generally intermittent and did not tend much toward chronic alcoholism. It was quite different with the sort of drinking which might be termed industrial drinking, the drinking that went with bad hygienic conditions, overcrowding, insufficient or unattractive food, overwork, and so on. It was characteristic of this form of drinking that it went on during working hours, and that it was more or less in substitution of food. It might not cause drunkenness except indirectly, but it inevitably led to chronic alcoholism. In the prosperous mining districts there was much drunkenness but little alcoholism, and the same might be said to a lesser extent of the agricultural districts. On the other hand, in the manufacturing towns, in which the industrial conditions were less favorable, there was much alcoholism; and in the seaports, in which these conditions were at their worst alcoholism, alcoholic suicide, and crime, reached their highest development. In these towns the alcoholism was accompanied by much drunkenness, though the drunkenness was not the cause of the alcoholism, but both were effects of a common cause in the industrial conditions. Statistics of drunkenness, therefore, were of no value as a measure of alcoholism. From a social point of view convivial drunkenness was at once much less important and much easier to check than was industrial alcoholism. The remedy for the latter form of drinking was to raise the standard of living, and something might also be done by restricting the facilities for obtaining alcohol during working hours by providing hygienic substitutes, and by sane and temperate teaching as to the proper use and limitations of alcoholic liquors.

There is certainly a dividing line between chronic alcoholism and convivial drunkenness, but the latter habit will perhaps in the majority of instances lead to the chronic state. Industrial alcoholism proceeds from misery, and the conditions of life which prevail in crowded manufacturing districts. At the same time some individuals are more predisposed to the use and more susceptible to the influence of alcohol than are others.

By rendering the conditions of life in large towns more hygienic and more pleasant the prevalence of alcoholism should be checked. As to whether prohibition laws are of much use is a moot point, and at any rate such legislation is contrary to the instincts of a free people. A great orator of the Church of England once said in the House of Lords that "he would rather see the people of England drunken and free than sober and slaves," and although the phrase was somewhat extravagant it aptly expressed the principles of free government.

Cholera in the Philippine Islands.

In the report of the Surgeon-General of the Public Health and Marine Hospital Service is an article on Cholera in the Philippines, by passed Assistant-Surgeon J. C. Perry. The article in question is of considerable length, so that but a part of it can be considered here. An interesting point in the account given by Dr. Perry is the likelihood of the disease being spread by the agency of flies. No other explanation of the dissemination of cholera in Bilibid Prison, Manila, than by means of food infected by flies will satisfactorily meet the circumstances. Surgeon Perry says, that after a careful consideration, I cannot believe that the history of the epidemic in Manila coincides with that due to an infection of the general water supply, and in my opinion the following factors were operative and causative in the order enumerated: (1) Infected food; (2) Contacts infecting their own food and possibly that of others; and (3) Infected water taken from shallow wells and from the Pasig River and the estuaries.

An attempt was made to compile statistics of

the number of cases and deaths in each province and island, but it was found impracticable on account of the inaccurate reports received from the provinces. Surgeon Perry, however, gives the statistics of Manila. From a study of these it is gathered that the Chinese did not suffer severely—in fact, not so much as the Americans in ratio of population. This may be ascribed to the habits of the Chinese. (1) The Chinese drink little water, using tea almost exclusively as a beverage, and (2) they do not eat with their fingers, as the Filipinos, always using chopsticks for conveying the food to the mouth; consequently there is less danger of infecting their food. Again, they rarely eat uncooked food.

The writer is of the opinion that the rather large number of Americans affected may be attributed to neglect of usual precautions, because for the first two months of the epidemic the number was small, but toward the end, even when the daily number of cases was few, the number of cases among Americans increased, tending to show that they had become lax in their precautions and were less careful as to their food and drink.

Surgeon Perry estimates that in the cholera epidemic in the Philippine Islands in 1902, there occurred in the provinces 173,619 cases and 109,703 deaths; adding to this the statistics for Manila would give a total of 179,689 cases and 114,274 deaths.

News of the Week.

The Canadian Medical Association.—The thirty-seventh annual meeting of the Canadian Medical Association was held at Vancouver, B. C., on August 22, 23, 24, and 25, under the presidency of Dr. Simon J. Tunstall of that city. As this was the first occasion on which the association had visited the western confines of the Dominion, it was feared that the great distance would interfere with the attendance of eastern members. Such fears, however, were groundless, as the convention was one of the most satisfactory ever held. The attendance was 270, about 150 coming from east of the Rockies, each province from the Atlantic to the Pacific oceans being well represented. As special guests of the association, there were present Drs. Dudley of Chicago, C. H. Mayo of Rochester, Minn., Mayo-Robson, McGillwray, and Sinclair of England. There were also present about fifty members of the profession from the Pacific States and others from the Eastern States, all of whom were made guests of the association, and invited to participate in the festivities as well as the discussions. A brief report of the scientific work of the meeting, from the special correspondent of the MEDICAL RECORD, will be published in a later issue. The concluding session, held in the morning of Friday, August 25, was purely of a business character. Halifax, Nova Scotia, was selected as the next place of meeting. The election of officers resulted in the choice of Dr. John Stewart of Halifax, president, Dr. George Elliott of Toronto, general secretary, and Dr. H. B. Small of Ottawa, treasurer. The visiting physicians were most hospitably entertained by their local brethren and by the residents of Victoria, which latter city was visited at the close of the meeting. A convention and reception, a drive to interesting points, an excursion to the salmon fisheries and the association dinner were among the many interesting gatherings. At Victoria, a drive around the city, a sail to the dock yard and quarantine station, and a reception at the Government House were tendered to the members.

International Congress of Arts and Science.—The organizers of this Congress, to be held at the Universal Exposition, St. Louis, September 19-25, 1904, desire to invite the special attention of the medical profession to the rare opportunity which it offers to meet and hear a great number of eminent men of learning. It is expected that more than three hundred well-known scholars of Europe and America will deliver discourses in the various departments and sections of the Congress, and that many hundred shorter communications will be made by those present. Among the foreign members of the profession who have accepted invitations to speak are Sirs Lauder Brunton and Felix Semon, and Professors Ross, Celli, Orth, Liebreich, Allbutt, Kitasato, and Escherich. Dr. William Osler is chairman of the department. It is the desire of the directors of the fair and of all concerned in the organization that professors and instructors in our colleges and universities, and members of the learned professions generally, shall, so far as possible, do honor to our distinguished visitors by attending the meetings of the Congress. For this no fee is charged, and no formality is necessary except enrolment on arrival. It is, however, desirable to apprise Mr. Howard J. Rogers, Director of Congresses, Universal Exposition, St. Louis, Mo., in advance, what departments of the Congress one desires to attend. A program of its proceedings, with such other instructions as may be necessary, will be sent by Mr. Rogers on application.

Missouri School for the Blind.—Work has begun on the new buildings for this institution, located at St. Louis, the old building having been sold to the School Board. There are to be eight buildings, so arranged as to be practically under one roof, and each building fireproof. The structures will have a frontage of 396 feet by 285 feet. The school will be divided into ten wards, fifteen schoolrooms and thirty piano rooms. Two enclosed gardens and playgrounds will face the front of the building. The total cost of the completed buildings will aggregate $300,000, appropriated by the State.

Health Officer Sued by a Dairyman.—The City Health Officer of New Orleans, Dr. Quitman Kohnke has been sued for $10,000 damages by a dairyman. The City Board of Health has also been temporarily enjoined from seizing the milk from the plaintiff's dairy. The Board had seized and thrown out some of the milk after ascertaining that there were two cases of typhoid fever on the premises, and very unsanitary arrangements for washing cans and watering the cows.

Druggists Charged with Contempt of Court.—Twenty-five hundred retail druggists in the United States were recently declared guilty of contempt of court by Judge Dunne of the Circuit Court of Illinois, and the National Association of Retail Druggists, of which they are members, was fined $2,000, while the secretary of the organization, was fined $500. The injunction for the ignoring of which the druggists' association was fined was secured by a retail druggist of Chicago, in November, 1902, and restrained the members of the association from interfering in any manner with the securing of supplies by the petitioner, who had incurred the association's displeasure.

Smallpox in Illinois.—There are nine cases of this disease quarantined at Belleville (Illinois), and three patients are at the County Isolation Hospital. East St. Louis (Illinois) is said to have from 300 to 400 cases; 35 of the 38 patients at the isolation hospitals are from East St. Louis. The disease exists in a number of houses at Centralia

near the Illinois Central Station. Peru has fifteen cases of the disease, and La Salle one case.

Dr. Vida A. Latham was recently elected secretary of the American Microscopical Society.

Case of Leprosy at Peru, Ill.—A case of this disease has been discovered at Peru. The patient is employed at the works of the Illinois Zinc Company. He is married, and is the father of seven children. The origin of the disease was not discovered.

The New Orleans Charity Hospital.—The Governor of Louisiana has reappointed as administrators of the Charity Hospital in New Orleans to succeed themselves, Mr. Louis Valloft and Dr. George S. Bel.

Result of Open-air Treatment.—Maj. Oliver B. Simmons, in charge of the South Mountain Camp sanatorium on the Pennsylvania State Forestry Reservation at Mont Alto, Franklin County, has reported that since the sanatorium for consumptives was opened in June, 1903, about sixty-five patients have been received, and at present there are thirty there, most of whom will spend the winter in the open. Of those who were received for treatment 50 per cent. have returned to their homes, apparently cured.

Radiumized or Emanated Wool.—According to a writer in a Russian newspaper, quoted in *The Lancet*, Dr. E. S. London has been studying the question of radium emanations, and his investigations lead to the conclusion that generally radium emanations do not differ in their physiologo-pathological action from the action of radium itself. Both inflame the skin and are destructive to various kinds of life. Dr. London carried out a series of tests with various substances which were subjected for some time to radium emanations and produced inflammatory effects on the skin, the most intense radio-activity being observed in the case of wool which, because of its sponginess, absorbs a large quantity of radium emanations. "Emanated" wool, according to Dr. London, offers, in the first place, the facility of easy distribution over the body, and it can be conveniently adjusted to any part, according to the needs of the case. In the second place, in the vehicle of wool radium becomes conveniently portable and radio-active energy, as in charged wool, can be sent great distances, since in hermetically closed vessels its radio-activity weakens very slowly. At the same time radio-active wool may become part of pharmaceutical stock, and at no great expense, for from five to ten milligrams of radium are sufficient to energize a large quantity of wool. However, as to this, Dr. London is careful to state that before making "emanated" wool an article of pharmaceutical commerce, we must know how and in what particular cases the commodity would be useful—and that is still a question for the future.

Business Committee of the Medical Society of the State of New York.—The president, Dr. H. D. Wey of Elmira, has appointed the following members of this committee: Dr. Henry Flood of Elmira, Dr. A. Edward Davis of New York, and Dr. Leo. H. Neuman of Albany. The committee has charge of the preparation of the program for the next annual meeting of the society, and may be communicated with by any one interested in it. The meeting will be held at Albany on January 31 and February 1 and 2, 1905.

Mount Carmel Hospital, Orange, N. J.—The hospital to be established on the grounds of the Jayne estate, the purchase of which for this purpose, by the Rev. Victor Romanelli, was recently announced here, will receive this name. The hospital will be equipped as quickly as possible, and will be opened about the first of November with thirty beds, besides a maternity ward and a children's ward. The institution will be non-sectarian. The sick poor will be admitted without regard to color, condition, or creed.

Dearborn Medical College.—On August 30 this college opened its new home at Michigan avenue and Twelfth street, Chicago, in the building formerly occupied by the Manual Training School. Addresses were delivered by Dr. Geo. F. Butler of Alma, Mich.; and Dr. Homer M. Thomas of Chicago. This medical night school begins with an enrollment of 200 students. The cost of remodelling and furnishing the building is approximately $10,000.

The Missouri State University School of Medicine.—This institution, located at Columbia, Mo., has a hospital with a capacity of fifty beds, a clinical amphitheater with a seating capacity of one hundred, and a large medical laboratory among the new features of the school. About twenty-five men, supported by salaries, who devote themselves to teaching, writing, and research, are in charge of the laboratories. The course of study is four years, and by a proper arrangement of courses a student may receive both an academic and a medical degree in six years.

Beth-Israel Hospital to Be Enlarged.—Plans have been filed with the Building Department for the enlargement of the new Beth-Israel Hospital, at Jefferson and Cherry streets, by the remodelling of a six-story tenement house at the southwest corner of Jefferson and Monroe streets. It will be connected by bridges with the hospital building and will be utilized as living quarters for the nurses.

Oak Park Hospital, Chicago.—It is planned by the committee on organization of the Oak Park Hospital movement to have a mass meeting early in September, at which the promoters of the hospital idea will present the proposition, and those present will be asked to subscribe toward the building fund. Officers will be elected, and the Oak Park Hospital Association incorporated under the State laws. It is said that the hospital, when completed, will not cost less than $125,000. There will be a separate building for infectious diseases, and a maternity building.

Englewood (Illinois) to Have a New Hospital.—A charter was recently granted to the Swedish-American Hospital Association of Englewood for a hospital. The capital stock is $100,000. The hospital will be in Englewood, but the site has not been chosen.

Carbonated Staining Fluids.—Food inspectors, who recently had an analysis made of the syrups served at soda-water fountains, in some of the Pennsylvania resorts, found a substance called "orangeade," compounded of a yellow anilin dye, benzoic acid, and saccharin. Handkerchiefs dipped in the syrup were dyed a brilliant yellow.

The Brooklyn Samaritan Hospital is soon to be established at Fifteenth Street and Fourth Avenue, that borough. The new hospital is the outgrowth of the dispensary work of the Fifteenth Street Baptist Church, in that neighborhood. It will, however, be non-sectarian.

Dr. P. A. Lovering, Surgeon U. S. N., has been ordered to the chair of tropical diseases at the Naval Medical School in Washington.

Medical Students and Graduates in the United States.—It is stated in the educational number of the *Journal of the American Medical Association* that the number of medical students in the United States for

the year ending June 30, 1904, was 26,138—1,477 less than in the year 1903. Of this number, 23,662 were in attendance at the regular schools; 1,105 at the homœopathic; 1,014 at the eclectic, and 357 at the physiomedical and nondescript schools. There was a decrease in the attendance of the regular schools of 1,268 below last year, and a decrease of 1,216 below the year previous—1902. In the homœopathic schools there was a decrease of 393 below that of 1903 and a decrease of 512 below 1902. The eclectic schools have been increasing steadily since 1900. In 1904, 1,014 students attended the eclectic schools, an increase of 166 over the attendance of the year previous—1903. The total number of graduates for the year ending June 30, 1904, was 5,747, an increase of 49 over the preceding year. The increase in 1903 over 1902 was 699, so that the increase during the present year was much less than that of the year previous.

A Shipload of Measles.—Forty-seven cases of measles were discovered among the children of a band of gypsies that arrived at this port recently on the steamship *Carpathia*, and the entire band, men, women, and children, has been detained at Ellis Island. Some of the patients have been sent to the hospital and the rest have been segregated.

Bequest to a Hospital.—By the will of the late John Lawlor Welsh of Philadelphia the sum of $50,000 is bequeated to the Hospital of the Protestant Episcopal Church in Philadelphia.

New Water System for Manila.—Major J. F. Case, city engineer of Manila, has laid before the Secretary of War and Chief of the Bureau of Insular Affairs at Washington plans for the proposed water supply and sewerage system of Manila. The plans have received the approval of the municipal board of Manila, and have been favorably reported upon to the Secretary of War by a consulting engineer sent to the Philippines some time since.

Obituary Notes.—Dr. Henry Tuck of this city died at his summer home in Seabright, N. J., on September 2, at the age of sixty-three years. He was born in Barnstable, Mass., in 1842, and was graduated in arts from Harvard University in the class of 1863. After studying medicine for two years he was appointed acting assistant surgeon in the army, and as such saw service during the closing months of the Civil War. He completed the regular course of medical studies and received his medical degree from Harvard in 1867, and after spending a year in the general hospital in Vienna, he began practice in Boston. After ten years' general practice, during which time he was one of the physicians of the Massachusetts General Hospital, and served as medical examiner and medical referee for several life insurance companies, he was elected medical director of the New York Life Insurance Company. He became a trustee of the company in 1878, senior medical director in 1883, second vice-president in the same year, and senior vice-president in 1885.

Dr. Elbridge G. Simons of Ripley, N. Y., was killed by a railway train near Cleveland, Ohio, on September 1. He was a graduate of the Bellevue Hospital Medical College in the class of 1875.

Dr. Millard Fillmore Cyphers died in Philadelphia on August 29, at the age of forty-five years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1887.

Dr. Julian Fajans died in Philadelphia on August 26. He was graduated from Jefferson Medical College in the class of 1886. He served during the Civil War in the One hundred and sixth Pennsylvania Volunteers, and the Nineteenth Pennsylvania Cavalry.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

OXFORD CEDES TO CAMBRIDGE—BRITISH ASSOCIATION—MR. BALFOUR PRESIDENT—CANCER DEMONSTRATION BY DRS. ROBERTSON AND WADE—NURSES AND REGISTRATION—PHARMACISTS AND DISPENSING—PERSONAL ITEMS—OBITUARY NOTES.

London, August 19, 1904.

Oxford this week gives place to Cambridge The one university seat has entertained medicine, the other science in all its branches. The British Association (we usually drop "for the advancement of science") is the mother of the numerous societies that have grown up among us on the same plan. This is the seventy-fourth meeting of the association, and the fourth time it has met at Cambridge. The first time was in 1833, under the presidency of Adam Sedgwick; the second in 1845, under Sir John Herschell; the third in 1862, under Professor Willis. This time no less a personage than the Prime Minister accepted the presidency, and he was naturally supported by many persons distinguished in other walks, as well as by the usual array of eminent men of science from all countries—a goodly proportion from your side of the Atlantic. There is something that seems appropriate in meeting at Cambridge at a time when physical theories figure largely in the scientific atmosphere, for her University has been called the birthplace of many of the most important of such theories from the time of Sir Isaac Newton to the present. The holders and promulgators of the latest notions on the constitution of matter assembled to discuss their views, and Mr. Balfour in his presidential address dealt with them from a philosophical aspect.

Cancer still holds the field as a subject of intense interest from many points of view. At Oxford there were two lantern demonstrations which your reporter briefly mentioned. One was by Mr. C. E. Walker, and illustrated the results obtained by him in conjunction with Professor Farmer and Mr. J. E. S. Moore as related last December to the Royal Society. I have already fully detailed their researches in your columns, and will therefore turn to the other demonstration which was by Drs. Ford Robertson and H. T. Wade, and which has led them to very different conclusions. Their investigations will especially interest you as they were begun with the view of testing the opinions held by Roswel Park, Gaylord, and other American observers, that carcinomatous tumors are the result of the invasion of an organism of the same nature as the plasmodiphora brassicæ. This has long been known to attack certain plants and produce in them tumors which are named club-root, finger and toe disease, and kohlhernie. Drs. Robertson and Wade think their investigation shows that minute organisms which only differ in size from the plasmodiphora brassicæ are present in cancer. The organisms are extremely difficult to stain, but by means of their reaction to platinum and to ammonio-silver, followed by gold toning, they can be demonstrated in the vegetable tumors above named and in carcinoma. But these organisms are only from $\frac{1}{20}$ to $\frac{1}{10}$ the size of the phasmodiphora brassicæ, though their morphology and reactions are identical. From three carcinomata Drs. Robertson and Wade have grown an organism which accurately represents the post-spore or pre-amœboid stage of a plasmodiphora. Thus the parasite theory is again put forward to oppose the cell theory, and we may wait for further investigations with an open mind.

Those nurses who are claiming state-registration are not likely to neglect any chance of posting their views At the late Congress of the Royal Institute of Public Health they put in an appearance, and three of them read papers repeating their well-worn opinions. They were lately met by a serious protest from hospital managers, but that makes no impression on them. They fancy that nursing is to be protected as a close profession, to be followed by those who enter it for life. But we know how many leave it for matrimony if they do not make it a step toward that object Their examinations, whether written or oral, can scarcely meet the requirements. The nurse may, like the midwife, pride herself on some certificate she calls a diploma, but the employer wants a "character." The word smacks of domestic service, but, after all, what is a nurse but a temporary servant to a sick person, and the doctor should control the attendant on his patient.

At the Pharmaceutical Conference of the 9th inst., the President, Mr. Idris, again raised the question of medical men dispensing their own prescriptions. He is a zealous advocate of the pharmacists' sole right to dispense, and with all the energy of trade instincts wants to confiscate by legislation the rights which medical practitioners have enjoyed from time immemorial. It is another instance of the insatiable greed produced by success. The chemists

and druggists of this Kingdom have succeeded in securing rights, in the struggle for which they were supported by doctors, and now show their gratitude by a scheme for despoiling their benefactors. It is true that one or two consultants are ready to aid and abet them in the name of the dignity of the profession. But, as I have shown you on other occasions, there are hundreds of practitioners who are compelled to give advice and medicine for a less price than Mr. Idris would charge for dispensing the remedy It is sad but a fact, and the professors will be mad if it suffers the counter-prescribers to rob it any more.

Dr. William Osler has been appointed Regius Professor of Medicine in the University of Oxford, in succession to Sir J. B. Sanderson.

Prof. Lorrain Smith of the Belfast College has been appointed to the Professorship of Pathology in the University of Manchester.

Sir Wm. Bennett has had the Cross of the Order of the Saviour conferred on him by the King of Greece.

Dr. A. S. Grünbaum will leave the Liverpool University to take the chair of Pathology in the Leeds University, *vice* Professor Trevelyan, who will retire at the end of next month.

Dr. Arthur Hughes, M.O H., for Barmouth, died suddenly on Sunday after running to catch a train.

Surgeon Major-General Tippetts has died at the age of seventy-two. He entered the army in 1854 and has a distinguished record He went to the Crimea, was in the battles of Alma and Inkerman and at the siege of the Sebastopol, for which he had the medal, three clasps, and the Turkish medal. He took part in the Afghan war, 1878-80, was mentioned in despatches and received another medal. He retired in 1892, having become Surgeon Major-General. He received the distinguished service reward in 1901.

Dr. Gowing of Swansea died, according to the verdict at an inquest, from an overdose of morphine while staying at a hotel at Maidenhead.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

GENERALIZED VACCINATION RASH MISTAKEN FOR SMALLPOX—THE WHITE BLOOD CELLS IN LEUKÆMIA—THE SICK-BENEFIT QUESTION IN BERLIN—DISCUSSION OF JACOB'S INFUSION TREATMENT OF TUBERCULOSIS—THE FIRST FOREST SCHOOL—DEATHS OF CARL WEIGERT AND ERNST BENNECKE.

BERLIN, August 13, 1904.

A GOOD deal of excitement was caused in Berlin early in July by the report, appearing in several newspapers, of a case of smallpox admitted to Baginsky's clinic. All persons who had come in contact with the case were strictly isolated and the patient, a boy of eleven, was transferred to the isolation ward of the Charité. Careful watching for a few days proved the case to be not true smallpox, but a generalized vaccination rash. Baginsky reported on the case at the meeting of the Medizinische Gesellschaft. The boy himself had not been vaccinated, as he was suffering from eczema, but had slept in the same bed with his brother who had been vaccinated and showed the ordinary vaccination pustule. A great number of very similar pustules were found scattered over all but the lower part of the body of the patient admitted to the hospital. His general health, however, was excellent, and Senator, as well as the other members of the medical staff, diagnosed the case as one of generalized vaccination rash.

At the same meeting, Litten read a paper on "The Behavior of Leucocytes in Leukæmia." By means of his differential stain, Ehrlich has shown that in inflammatory processes only the polymorphonuclear neutrophiles leave the blood-vessels. Later, Neisser demonstrated the emigration of eosinophile cells in a case of pemphigus; the same variety of leucocytes has since been found outside the blood-vessels in bronchial asthma and in Duhring's disease. We can explain this phenomenon only by assuming that the substances produced by different diseases attract different types of white cells. So far, only three observers have reported on the emigration of leucocytes in leukæmia. Polymorphonuclear cells only were found in the fluid from a blister, while ascitic fluid from the second case contained only mast cells, and all varieties of leucocytes were present in the pleural exudate in the third case. Litten himself, in a case of myelogenous leukæmia, found all the varieties of leucocytes in the serum from a blister. He is of the opinion that a careful examination of serous exudates in leukæmia would shed considerable light on the nature of the disease, and he urges that such examinations be made whenever possible.

I am sorry that the report on the question of sick-benefit lodges is quite unfavorable. The importance of this question is apparent to all who have read the statistics on invalid insurance which have appeared in the "Vierteljahrshefte für die Statistik des Deutschen Reiches." There are 23,214, sick benefit lodges with nearly ten million members and a combined capital of 200,000,000 marks ($40,000,000). Each member has on the average received sick benefits to the amount of 17.02 marks. While throughout Germany the physicians insist upon "freie Arztwahl," *i.e.* the right of a member to choose his own physician and the right of any physician to act as lodge doctor, this movement has not met with success in Berlin. We have in this city several associations of lodge doctors, the two most important being the Association of Lodge Physicians chosen by the members, to which belong almost all the physicians of Berlin, and the Association of Berlin Lodge Physicians, whose four hundred members are chosen by the directors of the lodges. Since July 1, two of the largest sick benefit lodges have annulled their contract with the first association and have installed members of the Association of Berlin Lodge Physicians as lodge doctors. In other words, the members of the sick benefit lodges are obliged to leave the physicians who for years have had their confidence and must consult the lodge doctor. According to the directors of the lodges, this system is more economical since it is easier for them to control a physician whom they have appointed and who is more dependent on the lodge than a physician chosen by a patient The whole fight is a purely political one, since the lodge directors are with few exceptions socialists with excellent organization, who endeavor to keep all other influences away from the lodges.

Naturally these occurences have aroused a lively interest in this city, which is, however, at the present somewhat overruled by the attention centered in the discussions of Jacob's paper, on which I reported in my last letter. Two sessions of the Verein für innere Medizin were taken up with these discussions, some of which found their way into the daily papers and caused a good deal of comment among the laity. Jacob and his method have been severely and adversely criticised. Oestreich doubts whether the encapsulations found in the lungs of the tuberculous cow were the result of the infusion only, and he furthermore thinks that the tuberculous process would probably invade the capsule, this being demonstrable only under the microscope. Westenhoeffer performed an autopsy in one case treated by Jacob's method, and found the condition of the lungs much resembling that demonstrated by Virchow in a case in the early days of tuberculin treatment, and he believes that in this case at least, Jacob's method aggravated the disease, causing "galloping consumption." Litten thinks that the liquid infused never reaches the apex and is absorbed too rapidly to be of any benefit. He has achieved results equal to those reported by Jacob with almost every other method of treating tuberculosis. F. Klemperer states that infusions have been made into the lungs of tuberculous deer by Botey, Heryng, and Mendel, and that Downie tried the treatment on man with a certain percentage of recoveries. But these methods have fallen into discredit, thus proving them to be of small value. M. Wolf, head of the Division for Pulmonary Diseases at the Charité, believes with Litten that he has obtained as good results from any one of the numerous methods of treating tuberculosis. He also gave a detailed account of his experience with Jacob's method in three cases. There was a more marked reaction in these cases than Jacob had observed, death following the infusion in from one-half to thirty hours, although Wolf used a smaller quantity of liquid. Upon section, the lungs were found to be atelectatic in places, while the infused liquid had not reached the apices. In these discussions Jacob was severely censured for experimenting on human subjects before the results of his tests on deer had justified such a course and for performing tracheotomy when this operation was not indicated.

Greater Berlin, that is, not the town itself but its sister city Charlottenburg, can boast of a new institution, the first of its kind in Germany, namely, a "forest school." The establishment covers about one hectare of ground and is surrounded by pine forests, which screen it from high winds. Green lawns and shrubbery delight the eye. The buildings include a school building, an open shed, a barrack for the management, and one used as a lavatory and bathroom. There are 120 pupils of both sexes, divided into six classes. The children are selected by the school physicians and consist of those who, while not ill enough to be sent to a hospital, are yet not sufficiently strong to get along in classes with robust, healthy children. The pupils spend the entire day at the school, where they are given three meals. The actual time for study is not to exceed two to two and a half hours, the rest of the day being spent in games, gymnastics, manual training, etc. After the midday dinner the children may rest or sleep in comfortable chairs. Dr. Bendix, Dr. Heubner's assistant, visits the school regularly to look after the health of the pupils. It is intended to keep the school open until October.

We have recently lost a member of the profession whose ingenious and careful labors, especially in the field of

pathology and bacteriology, have made his name known far beyond the boundaries of his native land—Carl Weigert. His methods of staining have proved of the greatest value in rendering elastic tissue, fibrin, and neuroglia apparent in microscopic preparations. He has also advanced our knowledge of the pathology of tuberculous affections.

Prof. Ernst Bennecke, one of the ablest of the younger teachers of surgery, has recently died in this city. He was for many years the assistant of Franz Koenig, and later became the chief of the surgical polyclinic at the Charité. He died, a martyr to his profession, of blood poisoning contracted during an operation. His most important work was a monograph on gonorrhœal arthritis

Progress of Medical Science.

Boston Medical and Surgical Reporter, September 1, 1904.

Surgery on Old Men.—Wm. H. Arthur, as a result of his experience at the Soldiers' Home, tells us that old men are much better surgical subjects than is usually supposed. He operated on twenty-two patients averaging seventy years of age, with recovery in all except one, a hopeless case of gangrene. We need not hesitate to operate on old men, he holds, for their chances of recovery are fairly good. The administration of anæsthetics to 586 old men, operated on in fourteen years, without any death, shows that the aged can take ether well.

Clinical Topography of Lymph Nodes.—F. J. Cotton tells us that most surgical affections of the lymph glands are of infective origin, secondary to some local focus of infection. The key to finding the source of infection is a knowledge of what regions are drained by a given chain of glands. The author considers the groups of glands regionally. Those of the head become swollen from furuncles, injuries of the scalp, pediculosis capitis, syphilis, nasal diseases, disease of the teeth and gums, etc. Many so-called "scrofulous" glands in the neck are tuberculous; many result from irritation of the scalp by pediculi. Superficial glands of the neck lie about the jugulars, and over or a little behind the mastoid; they drain the posterior scalp and the parotid region, and are often enlarged in pediculosis. The deep glands of the neck drain the tonsils, pharynx, mouth, etc. They are swollen in cases of disease of the tonsils and pharynx especially. The glands of the arm and axilla become enlarged from wounds and septic processes in the hand and arm. Those of the groin from the same causes in the leg and foot; if low in the groin they may be non-syphilitic, due to a septic focus in the foot or leg. Another important class includes true inguinal buboes, associated with gonorrhœa, but almost never due to it; they are generally due to a septic process under the prepuce.

Journal of the American Medical Association, Sept. 3, 1904.

Oral Infection and Sterilization.—M. L. Rhein refers to the lack of requisite training of medical undergraduates in dental principles, and believes that further endeavors should be made toward having proper instruction in dental principles in the medical curriculum. The most important thing in oral infection is proper diagnosis, which he briefly considers. Perhaps the most common form of oral infection is the simple alveolar abscess which is caused by the death of the pulp of the tooth, which becomes an easy pray to bacteria. The cure of this consists in the aseptic removal of every portion of the contents of the root canals, their thorough sterilization and subsequent hermetical sealing. He calls attention to the serious neglect by the general surgeon of the evil effects of mouth infection. Very few persons keep their mouths in an aseptic condition. As a rule a patient is carefully prepared for operation in every respect except that of the mouth, which frequently is filled with, septic, if not with purulent effluvia; yet the mouths of operator and assistants are covered with sterilized materials, etc. He leaves it to the imagination to picture the result of such conditions, especially in intestinal surgery

Further Studies of the Intracellular Bacterial Toxins.—Victor C. Vaughan states that the purpose of his paper is to briefly tell what he has accomplished along the line of study of intracellular toxins and to formulate the theoretical conceptions that have grown out of his investigation and he concludes that (1) the colon bacillus in its essential part is a chemical compound. His findings indicate that the germ substance has a definite chemical composition, and that cleavage occurs along a definite line under the influence of an acid. That the toxic, hæmolytic, hæmoglobin splitting, carbohydrate, and other groups are chemically combined in the cell, is indicated by the fact that they are not extracted by agents acting physically as solvents, but are separated only by those agents which split up molecules. (2) The colon bacillus is a chemical compound, in whose molecule has been demonstrated the existence of the following groups: Nuclein, amido, diamido, monoamido, carbohydrate, toxic, hæmolytic, and hæmoglobin splitting. There may be, and probably are, many other groups. (3) Every cell in the animal body contains complex molecules similar to those of the bacillus. (4) The reaction of the colon molecule and a body molecule or cell is chemical. (5) If this conception of the reaction between bacillus and cell be true, the formation of antitoxins is capable of an explanation, which seems simpler than any yet proposed.

Regenerative Changes in Cirrhosis of the Liver.—W. G MacCallum concludes that in the ordinary type of interlobular cirrhosis there is a primary destructive process leading to the disappearance of portions of the cell mantle surrounding the central vein of each lobule. The framework of the lobule persists but usually collapses and there is produced an irregular lobular mass in which the central vein is in places left more thinly covered by the radial strands of liver cells, or even completely exposed and surrounded only by the connective tissue framework. The remaining liver cells proliferate rapidly by mitosis and generally increase the size of the portion of the lobule which is left. In this process they sometimes assume temporarily almost the form of bile-duct cells. The connective tissue bands which run through the liver and separate these irregular hypertrophied remains of lobules consist of preëxisting connective tissue together with some which is newly formed. Numerous bile-duct-like canals course through these bands, and it is thought that these are produced by proliferation from the preëxisting bile ducts. That the canals are composed of proliferating cells is shown by reference to a fresh case in which mitoses were abundant in their walls and by the fact that they frequently sprout out to form isolated bulbous masses of new liver cells. The bile-duct epithelium and the liver cells are shown throughout these processes to be equivalent so far as the regeneration of the liver tissue is concerned

Medical News, September 3, 1904.

Hemorrhagic Paratyphoid Fever.—T. H. Evans reports a case of infection by the bacillus of Eberth, in which there was throughout a moderate daily rise of temperature, with many of the usual symptoms of typhoid fever, a Widal reaction being positive during the latter part of the disease The peculiar feature of the case was the presence of a hemorrhagic flow from the vagina, lasting five days, and occurring two weeks after the regular menstruation. The spleen was enlarged and tender. In the hemorrhagic form of typhoid the fever may be more moderate than usual, but during the late second or early third week hemorrhage occurs from one of the special mucous membranes or in the skin. The pathology is obscure. Some reaction probably occurs in the parenchyma of the mucous structures of the body. It has been suggested that the bacillus is more than ordinarily virulent, and attacks the walls of the smaller blood-vessels, predisposing to hemorrhage through the degenerated areas.

Intestinal Obstruction Following Appendicitis Operations.—Clarence A. McWilliams reports and classifies eighty-six cases of obstruction after appendicitis operations that he has collected from the work of various surgeons, and draws from them the following conclusions: (1) The rarity of intestinal obstruction is noteworthy. (2) Obstruction may follow an attack of appendicitis which has not undergone operation. In this series of eighty-six cases, 10 per cent. were such. (3) Obstruction may follow the "interval" operation: 9 per cent. belong to this category. (4) Obstruction is most apt to follow appendicitis with abscess formation. Eighty-one per cent. were of this class. Hence the necessity for early operation. (5) Mechanical obstruction may come on within a short time after the appendicitis operation. (6) Obstruction may occur years after the original attack, or operation, when it may come on suddenly in perfect health, or preceded by a period with symptoms denoting "partial" occlusion. (7) There may be several attacks of true, mechanical obstruction. Several attacks occurred in 8 per cent. of the fifty-seven patients who survived the first operation for obstruction. (8) 66.3 per cent. recovered after operations for obstructions; 33 7 per cent. died. (9) The small intestine was occluded in all of the fifty cases in which it was noted. (10) The cause of the obstruction was given in fifty-three cases as follows: Constrictions by bands in twenty-eight patients; volvuli in ten; kinkings, or angulations, in eleven; and internal hernias in four cases. (11) Gangrenous bowel was encountered in five cases, necessitating resection, resulting in three recoveries and two deaths. (12) We may expect a much smaller death rate in the future, due to the earlier recognition of the symptoms and their more prompt relief by operation. (13) Prophylaxis consists in operating upon appendicitis before the formation of pus, the use of as little drainage as possible, and the

least possible amount of handling of the intestines at the time of operation. (14) Vigorous abdominal massage with elevation of the hips may avert an impending obstruction. Frequent change in patient's position is likewise recommended. (15) Since the exciting cause is in many cases an attack of acute indigestion, patients should have their diet carefully regulated for from four to six weeks after an attack of appendicitis or after an operation.

New York Medical Journal, September 3, 1904.

Pruritus Ani.—A. B Cooke says that pruritus ani is met with chiefly in adult life, and men are more frequently the victims. Among the constitutional causes he mentions digestive derangements, diabetes, nephritis, gout, rheumatism, and diseases of the liver. One of the most frequent causes is fermentation in the intestinal tract. Among local causes he speaks of thread worms as well as any cause which produces catarrhal inflammation of the circumanal region. Pruritus ani may be a purely reflex condition, and here the generative and urinary organs are most often at fault. He summarizes the essential features of treatment as follows: Cleanliness, protection of the parts from friction and irritations of all kinds, with local applications according to the indications of the individual for the relief of the itching and the restoration of the altered skin to normal, and in exceptional cases, the destruction of the diseased skin, preferably with the chemical caustics.

A Study of the Vagus Reflex in Three Hundred and Eighty Individuals: a New Physical and Prognostic Sign in Pulmonary Disease.—Thomas J. Mays, from an analysis of the symptoms and conditions as they are developed by the vagus reflex in the 380 cases which form the groundwork of the study, draws the following among other conclusions: There is sufficient pathological evidence for believing that the integrity of the vagi is always impaired in pulmonary consumption. The vagus reflex is universally present in active pulmonary consumption, and is usually situated on the same side of the body as that on which the lung affection is found. It is present in about 80 per cent. of healthy people who have a family history of consumption. In healthy people without a family history of consumption it is universally absent, provided there does not exist a family or personal taint of alcoholism, insanity, or some other neurosis. There is an appreciable difference in the degree of vulnerability to consumption among healthy people below the age of thirty-five years, between those who have a family history of consumption and a vagus reflex and those who do not have the same, but after the above given age period this difference is eliminated. The vagus reflex is a valuable sign in the diagnosis and prognosis of pulmonary consumption, for it projects the family history of the potential consumptive into the present.

Chronic Splenic Anæmia—E. F Conyngham records the history of a patient, twelve years old, with a negative family history. The child was never well from birth. When five or six years old he had several attacks of epistaxis, none being very severe. When seven years old he was examined by several physicians because of severe pains in abdomen and an enlarged spleen was noticed. No blood examination was made. He was first seen by the doctor on September 27, 1902. He had had two bad attacks of hæmatemesis and melæna and was very anæmic in color. The spleen extends downward to within .06 c.m. of left pubic spine in supine posture and about .08 c.m. to right of median line; upward it has extended so far that the apex beat of heart is under fourth rib when sitting, the heart itself being almost horizontal, and its pulsations being very evident in the second and third interspaces; no murmurs, hæmic or otherwise. Pulse small, hard, and slightly irregular, 88 to the minute; respirations, 19; temperature 99.1° F. Red corpuscles, 3,648,000; whites, 3,300; hæmoglobin, 40 per cent. On March 31, red corpuscles, 2,875,000; whites, 2,800; hæmoglobin, 30 per cent. Circumference at the navel was 81 c.m. On April 28, the white count shows 2,400. On June 14 the hæmoglobin was 40 per cent. The spleen had diminished to about middle line and apparently adherent to anterior abdominal wall. The lower end was distant .085 c.m. from the pubic spine. Heart sounds were notably accentuated with apex beat in fourth interspace. This patient was treated with iron preparations, which seemed to predispose to gastric hæmorrhage, then with arsenic, under which there seemed a progressive loss of strength and vitality. This was changed later, and directions were given to administer three times in the week small doses of sodium phosphate, with bone marrow after each meal, that the child be not exposed to sudden changes of temperature, and that all sweet foods and articles of diet subject to fermentation be withdrawn. Since then there has been a slight but gradual improvement.

American Medicine, September 3, 1904.

Hypertrophy of the Lingual Tonsil.—J. J. Richardson describes the lingual tonsil as consisting of a number of lymphatic follicles embedded in the submucous tissue between the circumvallate papillæ and epiglottis. They are the seat of all the diseases which may attack the other tonsils, and of some peculiar to themselves. Hypertrophy accompanied by dilated veins is the commonest disease condition. The symptoms of most importance are cough and changes in the voice, with feelings of a foreign body in the throat. The cough is hard, ineffectual, and brings about no expectoration. There may be hemorrhage from the rupture of veins. Globus hystericus may come from the swelling. Fatigue in singing and speaking, with inability to reach the high notes is common. Asthmatic attacks and spasm of the glottis may be results. The best treatment has been found to be removal by the tonsillotome. Cauterization has not been found as satisfactory.

Meteorological Conditions in the Causation of Lobar Pneumonia.—J. M. Anders has tabulated the data recorded by the United States Weather Bureau for a period of ten years (1876 to 1885), as to their effect on the occurrence of pneumonia. From the statistics of Grimshaw, in Dublin and London, it appears that the fatality and prevalence of pneumonia do not correspond to that of bronchitis, which is more prevalent in spring and summer. The author draws the following inferences from his tabulated statistics: The seasons exert a marked effect upon the prevalence of lobar pneumonia, the maximal mortality being observed during the winter and spring months. Insular climates probably manifest the greatest rise in pneumonia mortality in winter, while that of continental climates coincides mainly with spring. The mortality of the epidemic form of the disease is influenced by the seasons, and may occur in the fourth, and even third quarter of the year. An apparently close relationship exists between periods of low temperature and the death rate from pneumonia. The mortality rises and falls with the barometric pressure, the maximal level being reached during periods of highest pressure and *vice versa*; that the barometric pressure, however, is governed by the temperature, being inversely as the latter, is to be recollected. The average velocity of the winds and the death rate from this disease would appear to stand to one another in the relation of cause and effect. The coincidence of existing low temperatures, high barometric pressure, the direction and velocity of the winds, and the maximum mortality from pneumonia, is so uniformly constant as to merit serious consideration. The major influence exerted by the seasons, is indirect, in consequence of closed doors and windows, and lack of free ventilation.

The Significance of a Heart Murmur.—James S. McLester divides all heart murmurs into those due to organic disease, and those occurring in a heart that is structurally normal, or accidental murmurs. These last occur in anæmic and nervous persons, or when the organism is in some way below par. They are systolic, best heard in the pulmonic interspace, and vary greatly in intensity at different times, and in different positions of the body, while exercise, respiration, and position have more effect than in organic murmurs. They are often loudest when the subject lies on the back, and at the end of inspiration. They are soft, blowing, and high in pitch. There are no other physical signs of heart disease present. They are probably cardiorespiratory in origin. Their prognostic significance is good, as they usually disappear with their accompanying condition. In the case of organic murmurs a careful physical examination is necessary for the formulation of a correct prognosis. The history of rheumatism is of great value, and the rhythm and point of maximum intensity of the murmur are of importance. A murmur that accompanies the normal heart sound is of less gravity than one that replaces it. Postsystolic murmurs indicate a mild lesion, late diastolic ones are most grave. The intensity of a murmur is of no value in prognosis. Aortic insufficiency is most grave, sudden death often occurring; if the lesion is a result of arteriosclerosis it will be progressive; mitral stenosis is the next in gravity; after this comes aortic stenosis. The presence of compensatory hypertrophy makes the prognosis better. The extent of the heart lesion is of the greatest prognostic value. If the heart beats forcibly and well the lesion is a small one; a weak intermittent pulse is a danger signal. Cardiac valvular disease is more serious in children and old people than in adults; habits, mode of life, occupation, and temperament are important factors in prognosis

The Lancet, August 27, 1904.

Meningeal Infection by the Diplococcus Pneumoniæ, Simulating Infective Cerebrospinal Meningitis.—W. G. Barras reports the clinical history of a case which pre-

sents several features of interest analogous to those met with in some cases of epidemic or infective cerebrospinal meningitis, but differing from the latter in that it was due to an accidental and somewhat unusual infection by the diplococcus pneumoniæ. From the clinical data, supplemented by the results of post-mortem and bacteriological examinations, the case was instructive in so far that it was reasonable to suppose that cases of a similar nature in which the diagnosis is that of ordinary meningitis might be due to a like infection. Meningitis the result of infection by the diplococcus pneumoniæ is generally secondary to an attack of acute lobar pneumonia, as the result of extension from disease of the nose and ear, or from the effects of an injury to the skull. In this case, however, no such conditions existed, and it can therefore only be regarded as a primary pneumococcic infection.

Note on the Serum Treatment of Exophthalmic Goiter.—George R. Murray says that the evidence which we at present possess tends to show that the symptoms of this malady are due to the morbid condition of the thyroid gland and are the result of an excessive formation and absorption of thyroidal secretion. The symptoms may be regarded as being due to a toxæmia the source of which is the diseased thyroid gland, just as much as the toxæmia of diphtheria or tetanus is due to the production of toxins in the locally infected area; and although we have no reason to regard Graves' disease as infective in origin he sees no good reason why an antitoxic serum should not be obtainable by suitable methods similar to those employed in the case of the infective diseases. A rational method of preparing an antitoxic serum appears to him to be by treating an animal with gradually increasing doses of thyroid extract so as, if possible, to induce the formation of antibodies in the blood and then to make use of the serum in the treatment of Graves' disease. Although no very definite results were obtained in the two cases he reports, he thinks it is quite possible that if larger animals than rabbits were employed and larger doses of the thyroid extract given a serum might be obtained which could be used for hypodermic injection in acute cases or for administration by the mouth in chronic cases in which prolonged treatment would be required.

A New Pathogenic Bacterium Causing Basal Meningitis in Infants.—W. D'Este Emery reports three cases in which an organism, quite unlike any known pathogenic bacterium, was isolated in cultures once during life from the cerebrospinal fluid and twice after death from the meningeal exudate and also from the pus from the middle ear. He reserves a fuller account for a future occasion. It was seen in films from the lumbar puncture fluid, from the meningeal lymph or pus, and from the tympanic pus in all cases. It seems fairly certain that it must be regarded as being the cause of the disease in the first two cases and as an important secondary infection in the third. The association of pus in the middle ear in all three cases, and the presence therein of the same organism as was found in the brain, is of some interest in connection with the etiology of the disease and of meningitis in general. It is, of course, impossible to say whether the brain was infected from the ear or *vice versa*. A point in favor of the view that the ear became effected secondarily is the fact that in the first case no pain in the ear was noted until the day before death, whilst in the second case there was a discharge from the nose, suggesting another possible source of infection. It is very unfortunate that this discharge was not examined bacteriologically. In this case, too, it is noteworthy that there was no notice of any symptoms pointing to pain in the ear, suggesting that the inflammation may have come on whilst the patient was semi-comatose; further, the ears were examined on admission and the tympanic membranes were found to be normal. On the other hand, in the few cases of septic meningitis following injury in which he has had an opportunity to examine the ears there has been no suppuration, suggesting that purulent inflammation does not easily travel in that direction.

British Medical Journal, August 27, 1904.

A Plea for Oral Hygiene.—Kenneth W. Goadby considers oral sepsis as an important factor in gastrointestinal disease. The affection is chronic and simulates acute diseases of all kinds, producing septic anæmias that appear to result from other causes. Dental caries is only a determining factor, the probable cause being microbic, and the constant swallowing of pus from the inflamed gums, with living organisms and toxic bodies, slowly develops the signs of secondary anæmia, of gastrointestinal disease, or of neurasthenia. Among children we find impaired nutrition, and impaired growth, resulting in badly developed maxillæ. The author gives the etiological factors as follows: crowding of the teeth, rachitic conditions associated with nasal obstruction, imperfect maxillar development, abnormality in size of tongue, irregular surface and deformity of teeth, soft foodstuffs, mainly carbohydrate, absence of mechanical effect of hard, fibrous material in food, alterations in oral secretions. Inflammatory sequelæ of acute fevers, diphtheria, etc., are frequent. Chronic lymphatic infections may result, anæmia from swallowing of staphylococci and impaired general condition. The remedy for these conditions the author sees in measures to secure the proper cleansing of the mouth and teeth from babyhood among the children and young adults of the working classes. This may be done through the dispensaries and the health officers of towns and cities.

Deutsche medizinische Wochenschrift, August 18, 1904.

Sweating as a Relief to the Kidneys.—H. Strauss has examined the sweat induced by dry heat in a large number of patients suffering from nephritis and other diseases in which the induction of perspiration was indicated as a therapeutic measure. Strauss believes that we must designate the sweat as a fluid which is as a rule hypotonic, and only in rare cases, such as uræmic conditions, either isotonic or hypertonic. In comparatively rare instances the sodium chloride content approaches that of the blood. It may occur in cases of nephritis, but is apparently no more frequent than in rheumatic and neuralgic conditions. The author's results seem to confirm the well known fact that sweating removes more fluid than solid constituents from the body tissues. There are exceptions, however, to this rule, and there are cases in which the sodium chloride content of the sweat equals that of the blood serum. The percentage of nitrogen in nephritis is often higher than that in the blood serum of non-nephritics.

Etiological Diagnosis of Typhoid Fever.—Jürgens comments on the uncertainty of known methods of bacteriological and serum methods in this disease. The numerous conceptions advanced are very confusing, and he believes that many cases diagnosed as paratyphoid, are etiologically not distinctive, but are merely instances which are noteworthy because of the peculiarities of their serum reaction, or are cases of ordinary typhoid fever, or finally may not be typhoid at all. A few cases have been observed which cannot be clinically differentiated from typhoid, but are found to have been caused by Schottmüller's bacillus, instead of by that of Eberth. Jürgens thinks that typhoid fever cannot be considered as a unit from the standpoint of etiology, and the distinction is merely one of terms, whether the cases in which the Eberth bacillus is not present shall be designated as paratyphoid, or whether they shall be included under the general term of typhoid, with a modified etiology. But the latter can only be spoken of when the symptoms of typhoid fever are present, and the bacillus of Eberth can be excluded with certainty as the cause of the disease.

Berliner klinische Wochenschrift, August, 15, 1904.

Scopolamin-morphine Narcosis.—B. Korff, who has devoted a great deal of time to investigations in this subject and has already published several papers on his experiences, contributes some further data. He reiterates his previous statement that absolute unconsciousness does not come on, and that when incision of the skin, peritoneum, or nerve trunks causes pain, it is well to wait a few moments before proceeding with the operation, as quiet again follows. Absolute quiet in the conduct of the operation is imperative, as the patient is really in a slumbering condition. If this precaution is observed, the addition of chloroform or ether will usually not be necessary. The author's principal conclusions as the result of over 200 cases of this method of narcosis are briefly as follows: The method is a suitable substitute for the inhalation methods in doses of scopolamin 0.001 and morphine 0.025. One third of this total should be given two and one half hours, the second third one and one-half, and the final third one-half hour before operation. In this dosage there is no danger of interfering with the action of either the heart or the lungs. Disturbances of other organs have not been observed. The method dispenses with the services of a special assistant for the anæsthetic. The reaction varies with the individual, and in some cases it may be necessary to strengthen the action by the addition of another dose of scopolamin 0.0002-3 and morphine 0.005-0.01, or a few drops of chloroform or ether. Larger doses than those indicated should not be employed. The only precaution necessary is to avoid the dropping back of the tongue, which is liable to occur in the deep sleep during and following the operation. Nausea and vomiting with their accompanying annoyances are absent and the patient may take fluids soon after operation.

Treatment of Biliary Calculi.—Konig presents a number of cases for the purpose of elucidating the methods employed for the simpler varieties of cholecystitis and cholelithiasis at the Charité in Berlin. The diagnosis is

usually based on the presence of a palpable sensitive tumor in the region of the gall-bladder, attacks of colic, and a mild icterus. In some patients the colic may be absent and there is merely a feeling of discomfort. The situation of the tumor may also be atypical. The presence of syphilis of the liver, with or without the formation of gummata, must also be considered. The so-called ideal cystotomy, by which the gall-bladder, after removal of the calculi, is closed, he does not recommend, and claims that better general results will follow the operation by which a biliary fistula is created. When the patient is fairly thin, he sutures the gall-bladder to the abdominal wall, passing the sutures through all the layers, one at the lower end one at the upper angles of the wound. When there is a great deal of fat in the abdominal wall and the bladder is small, the skin is not included in the sutures, only muscle and peritoneum. When the gall-bladder is large and freely movable, the patient is turned over on the right side after the abdomen is opened, the bladder delivered through the wound, incised, and emptied. The abdominal wound is then closed until merely sufficient room remains to include the incised section of the gall-bladder, and the latter sutured to the abdominal wall. The resulting fistula is apt to remain longer than in the other cases, but this the author does not consider a disadvantage. If necessary the line of junction between the skin and mucous membrane may be removed by a circular incision and the gall-bladder closed by a double row of sutures. The skin wound is not entirely closed, but left open for a time at the center. Ulcerative perforation of the gall-bladder, Konig declares is not necessarily accompanied by a bad prognosis, even when pus is emptied into the abdominal cavity. It is not nearly so dangerous as perforation of the gut.

Munchener medizinische Wochenschrijt, August 16, 1904.

Cardiac Weakness and the Injection of Morphine.—O. Rosenbach has repeatedly claimed that morphine, in both acute and chronic forms of so-called cardiac weakness, in attacks of stenocardia and pulmonary œdema, is of the greatest value, and his increasing experience has strengthened his views. The present communication is largely in the nature of a polemical discussion. In certain cases of cardiac disease, the fatal issue is often attributed to the morphine injection given during the attack. This he denies, and states that in any individual case the chances would have been very uncertain even without the administration of the drug, and that it is unfair to attribute to the latter the cause of the death.

Disinfection of the Biliary Passages.—F. Kuhn publishes the results of his observations on the application of the data already previously obtained by laboratory experiment, in the human subject. The summary of his results is as follows: Bile derived from a biliary fistula shows a constantly increasing fermentation, which is completed at the end of from twenty-four to sixty hours. The administration of salicylates, menthol, and similar drugs interferes with this process, and the effect appears within a day or two, and persists even after the administration has been stopped. This condition in the case of salicylic acid lasts about five or six days, and may also be demonstrated in the urine. The most suitable remedy for inflammatory processes in the biliary passages is salicylic acid and its salts.

Results of Serum Treatment in Acute and Chronic Articular Rheumatism.—Menzer reported about two years ago a number of cases which he had treated with antistreptoccus serum with good results. The present communication deals with the protective value of this treatment against future attacks and the production of cardiac complications. In forty-seven acute cases, twenty-five remained perfectly well after the elapse of a year or more, one had a recurrence, and the remaining twenty-one could not be reached for examination. In eleven chronic cases, a permanent cure extending over the same length of time could be ascertained as having resulted in nine—the other two could not be traced. The author acknowledges that the endocarditis cannot be prevented but it seems to be very favorably influenced, and better final results are noted than with other plans of treatment. The contraindications are based on the facts that chronic inflammatory foci may become acutely inflamed, and the reaction called forth makes certain demands on the strength of the patient. It should therefore not be given in the presence of a pericarditis, or a pleuritis with exudation, or a stenosis of any of the cardiac ostia. It is also contraindicated in very much emaciated individuals suffering from chronic rheumatism, unless the remedy is given in smaller doses at considerable intervals.

French and Italian Journals.

Contribution to the Semeiology of Acquired Endocarditis in Infancy.—Mario Vianello Cacchiole has collected sixty-seven cases of acquired endocarditis in infants, seen from 1894 to 1903 in the clinic for children at Florence. The most important symptom, and that first observed, is a systolic murmur, with greatest intensity at the the apex of the heart, due to growth of vegetations on the valves, usually the mitral valve. In the beginning of a mitral endocarditis the murmur is heard only at the apex; in acute cases, for a few days the murmur may be heard all over the chest; the action of the heart is tumultuous, the dyspnœa marked, and the pulse very rapid. As the disease subsides, the murmur is heard only to the left of the sternum and loudest at the apex Murmurs are better localized than in adults. The aortic murmurs are rare, as are also the pulmonary. The cardiac area is increased toward the left, there are an inconstant fremitus, a marked carotid pulsation, and a rapid, strong pulse, sometimes irregular. If the child recovers, compensation is good; the murmur is harsh, hypertrophy is seldom great, and dilatation is rare. The absorption of the inflammatory products is more rapid in the child than in the adult—*Rivista di Clinica Pediatrica*, August, 1904.

Primary Cylindrical Cell Carcinoma of the Lung.—Alfredo Bevacqua reports a case of cancer of the lung because of its rarity as a primary condition, and of its difficulty of diagnosis during life. The condition simulates entirely that of pulmonary tuberculosis. The patient was a man thirty-nine years of age, who came to the hospital to be treated for syphilis, having enlarged glands and tibial pains. He had at first no pulmonary symptoms; later a bronchial catarrh developed, then signs of consolidation in the lower lobe of the right lung. No tubercle bacilli were found in the sputum. A cavity formed and the patient died with all the symptoms of pulmonary tuberculosis. The autopsy showed characteristic lesions, apparently of tuberculosis in the lung and kidney, but when the microscopical examination was made it became evident that there was a new growth in the lung, a cylindrical celled carcinoma, which had originated from the epithelium of the bronchi. There was no other deposit except the small one in the kidneys, which was evidently secondary.—*Giornale Internazionale delle Scienze Mediche*, July 31, 1904.

Importance of Daily Weighing in the Case of Patients Suffering with General Dropsy.—Jules Courmont and Genet declare that the daily weighing of patients is most valuable as a source of information to the physician. It is very interesting to watch by this method the effect of various drugs in certain diseases, such as heart disease and Bright's disease. The writers have observed from their experience that digitalis and theobromine not only increase the aqueous part of urine, but also the salts voided in the same. In one case a patient voided a liter of urine containing about 4 to 1000 per cent. of salt. After the administration of digitalis, the same patient voided 3 liters of urine. But instead of 12 grams of chlorides eliminated in the twenty-four hours, there were 18. The same results are obtained by the use of theobromine. The amount of chlorides eliminated is even superior to the diuresis. In patients suffering with Bright's disease, theobromine has the most happy effect. Digitalis acts, but in a less degree. In patients suffering with heart disease, digitalis alone has good effects, theobromine being at times even harmful. The curve of weight of dropsical patients is in general in inverse ratio to that of the quantity of urine voided, but this relation is far from exact. But it indicates very accurately if the elimination of the chlorides is more, equal to, or less than the ingestion. If, for example, the weight decreases, elimination is greater than ingestion. In this way the treatment of these patients can be easily directed. It is an ingenious method of learning the permeability of the kidneys without preserving the urine.—*Lyon Médical*, July 31, 1904.

The Treatment of Tuberculosis by Marmorek's Serum.—A. Klein and D. Jacobsohn in reviewing their experiences in the treatment of tuberculous patients, state that nothing is more natural than accidents in the use of serum. Nevertheless, a number of their patients have undergone the treatment without any untoward results at all. These accidents, when they do occur, however, are only those which are commonly noted in the use of all serums. Aside from the fever which often accompanies the urticaria, a slight rise of temperature has been noted after the injection. The temperature in these cases sometimes rises several tenths of a degree, and persists as long as ten hours, after which it gradually falls. Sometimes there are articular pains following an injection. These are generally fleeting, and of short duration. In certain cases, however, they assume a more violent character, with spasmodic contractions of the muscles which surround the joint, even causing functional impotence, to a degree. This usually happens in cases in which the tolerated dose has been exceeded a number of times. The duration of the arthralgia never exceeds forty-eight hours. The urticaria from the use of this serum has the same characteristics as the same

eruption has after the use of other serums. It is most often localized at the inoculated region, but it sometimes becomes generalized and is accompanied by a considerable rise of temperature. Erythema also sometimes appears. In certain cases, the patient complains of weakness, loss of appetite, and general fatigue. These symptoms mean nothing in relation to prognosis, but their presence is an indication to diminish the dose now and then, but especially, to make the periods between doses longer.—*Bulletin Général de Thérapeutique*, July 30, 1904.

The American Journal of the Medical Sciences, August, 1904.

A Study of Circumscribed and Diffuse Pulsation of the Wall of the Thorax, with the Report of a Case of Pulsating Hæmothorax.—Joseph Sailer gives the following summary of his paper: Pulsation of the wall of the thorax may be due to disease of the heart or blood-vessels; may be idiopathic, that is, not the result of any definite cause, may be due to pleural or pericardial adhesions; to accumulation of fluid in the pleural cavity, or to abscess of the wall of the thorax. When the pulsation occurs as a result of accumulation of fluid in the pleura the left side is affected in the majority of cases. The patients are usually males and less than forty years of age. The mechanism depends in all probability upon the existence of a positive pressure in the pleural cavity with tension of the mediastinum.

A Study of the Tubercle Bacilli Isolated from Three Cases of Tuberculosis of the Mesenteric Lymph Nodes.—Theobald Smith states that the bacilli from these three cases of presumable food infection do not correspond to the bovine type of bacilli in any one particular. They were readily cultivated from nearly all the guinea-pigs inoculated, and they grew luxuriantly from the start on dog's serum. Morphologically the bacilli were either fairly long, *i.e.* they averaged about 2 μ in length, or else they were very variable, polymorphic. The uniformly short, straight forms of the bovine type were absent. In all cases the bacilli were of a very low order of virulence, lower even than that of many of the cultures of human origin studied before. None presented the reaction curve of true bovine bacilli. The writer concludes by saying that we have as yet no satisfactory evidence concerning the degree of change, if any, which tubercle bacilli of bovine type may undergo in the human body. He believes that it is at present quite inconceivable that changes could be as thoroughgoing as would be the case if we were inclined to attribute these cases of infection by way of the digestive tract to milk. He believes that we must refer them to infection with bacilli of strictly human origin.

The Leucocytosis of Pregnancy, of the Puerperium, and of Eclampsia.—Ralph Waldo Lobenstine concludes from the cases he has studied that: (1) The toxins of eclampsia cause, in most instances, a leucocytosis. The exact cause of this it is as yet impossible to explain. (2) All things being equal, the degree of the leucocytosis seems to depend very closely upon the degree of toxicity of the patient. (3) The greater the resistance of the patient, the higher the leucocytosis. (4) A sudden increase in the leucocytes generally indicates an aggravation of the disease in an individual with good resistance. (5) A low leucocyte count in a highly toxic patient is of bad omen. (6) A leucocytosis originally high that falls rapidly in a badly toxic patient is likewise a danger signal. (7) There is no direct return between the leucocyte curve and the temperature curve.

Orthostatic Albuminuria.—Charles Louis Mix is of the opinion that those cases which show the intermittent type of physical signs found in non-neurasthenic adults, with possibly a slight lowering of the specific gravity, even without the presence of casts, much more in their presence, should be regarded as cases of true organic renal disease. Those cases of continuous orthostatic albuminuria occurring in neurasthenic or hysteric adults, with unimpaired specific gravity and negative microscopic findings, should be regarded as functional in origin, with a relatively good prognosis. Cases occurring in children and associated with infectious diseases, should be regarded as cases of true nephritis, very likely glomerular. They may recover. Cases in children, associated with movable kidney, or with no apparent cause, especially familial cases, should be regarded as functional, with a good prognosis. The amount of albumin is of no prognostic value. The habits of life of the patient will influence the prognosis, however. The writer believes that in time there will be no disease of orthostatic albuminuria, *per se*, any more than there are at present diseases known as oxaluria, phosphaturia, or indicanuria, but it will be looked upon in various cases as a symptom, derangement, or defect.

Œsophageal Neuroses.—A. L. Benedict limits his discussion of this subject to motor neuroses. Absolute atony or paralysis of the œsophagus is very rare, if ever present. Hypotony, ordinarily called atony, is a very common condition. It is liable to develop into dilatation, whether of œsophagus, stomach, or intestine. Its diagnosis is somewhat difficult. Spasms of the œsophagus may theoretically, be divided into those of the circular, longitudinal, and both sets of muscles and classification not warranted clinically. Clonic spasm occurs mainly in connection with similar spasms elsewhere, especially of the sis is somewhat difficult. Spasms of the œsophagus may, theoretically, be divided into those of the circular, longitudinal, and both sets of muscles and classification not warranted clinically. Clonic spasm occurs mainly in connection with similar spasms elsewhere, especially of the stomach during vomiting. Tonic spasm of the œsophagus usually occurs in one of two forms: either a dysphagia analogous to that of organic stricture, or the spasm may assume the form of a moving globus (hystericus?) Occasionally tonic but more often clonic spasm is due to some well-defined reflex cause, at a greater or less distance. One form of globus, quite different from an hysterical manifestation in the ordinary sense, occurs after prolonged sobbing, laughing, etc. Air-swallowing always accompanies ordinary deglutition, thus there is often a belching of air during or after a meal. Aërophagia, as a neurosis, means almost any gradation between air-swallowing in the literal sense and a hiccough. In typical aërophagia, the condition is an hysterically magnified hiccough.

Pseudomelanosis of the Hæmolymph Glands.—Aldred Scott Warthin reviews three cases in which the striking common feature is the grayish or black discoloration of the retroperitoneal hæmolymph nodes in the absence of any similar discoloration of the spleen or other abdominal organs. The writer explains this phenomenon as due to the combination of hydrogen sulphide and the iron-containing blood pigment found in the phagocytes in the sinuses of the affected nodes. As to the source of the gas, it is evident that it was formed not in the intestinal canal, but in local infected foci or in the blood. In the first case there was a general colon bacillus infection arising from the infected seat of operation in the vagina and pelvis. In the second case there was a saprophytic infection of a bed-sore, with secondary involvement of the left psoas. In the third case there was a strong odor of the gas in the peritoneal cavity and abdominal abscess. From these regions was isolated a bacillus belonging to the colon group. It is probable that the formation of gas began before death, and that the appearances of the hæmolymph nodes were not entirely the result of post-mortem changes and conditions. This is certain in one case. The combination of H_2S with the iron-containing blood pigment of the nodes seems to be a satisfactory explanation for the pseudo-melanosis in these three cases. The writer concludes that it seems most probable that the pseudomelanosis of the hæmolymph nodes in all of these cases was due to an absorption of hydrogen sulphide from the blood or through the tissues rather than to a local formation of gas in the sinuses of these organs.

Two Thousand Operations for Appendicitis, with Deductions from Personal Experience.—John B. Murphy refers to his first operation in its modern sense, for appendicitis, as being performed in 1889. As to the etiology, the affection most commonly follows exposures such as would produce so-called "cold" of the respiratory tract. Foreign bodies were present in a little less than 2 per cent. of the cases. Fecal concretions were found in 38 per cent. Indiscretions in diet appear to have little if any effect as an etiological factor. The symptoms occur generally in the following order. Pain in the abdomen, sudden and severe followed by (second) nausea or vomiting, even within a few hours, general abdominal sensitiveness, most marked on the right side, or more particularly over the appendix, and elevation of temperature. When this order of the symptoms varies, the writer questions the diagnosis. He divides the time for operative intervention into four stages: First, early within the first forty-eight hours; second, in the active increasing inflammatory process, from the fifth or seventh day on; fourth, in the intermediate stage—between attacks. The most favorable time for operation is within the first forty-eight hours of the attack. The final results in appendicitis, as a whole are very gratifying. The writer declares that the obligation of the surgeon is to conduct a case of appendicitis to a favorable termination with the least hazard or risk to the patient, regardless of his personal feeling. The man who is having more than three or four deaths in a hundred operations is either receiving his patronage from incompetent and procrastinating physicians, or he is doing too much manipulating in the peritoneal cavity under unfavorable pathological conditions. As to transportation of the patient, the writer believes that if the patient is seen before the thirtieth hour, he can be transported to the hospital with safety. If it is after that time, the operation should be at home. If the patient is transported, he should be kept in the sitting position on the stretcher.

Book Reviews.

A Textbook of Diseases of the Nose and Throat. By D. Braden Kyle, M.D., Professor of Laryngology and Rhinology, Jefferson Medical College; Consulting Laryngologist, Rhinologist, and Otologist St. Agnes' Hospital; Bacteriologist to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases; Fellow of the American Laryngological Association, etc. Third Edition, Revised and Enlarged. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

In the five years this book has been before the profession its position has become so well established that nothing remains to be said by way of introduction. Laryngology is not as rapid in its progress as some other branches of medical science, bacteriology for example, yet it keeps pace with the advance of medicine in general, and in the three years since the publication of a second edition of this work, sufficient material has accumulated to justify the issuance of a new and revised edition. Most of this new material is to be found in the chapters on keratosis, influenza, correction of deformities by paraffin injections, cancer, hay fever, and deformities of the septum. The pictures are very good, twenty-four of the 175 illustrations being in colors.

Die Fruchtabtreibung durch Gifte und andere Mittel. Von Prof. Dr. L. Lewin. Berlin: Aug. Hirschwald, 1904.

This work of 350 pages is intended by the author to serve as a manual for physicians and jurists, and seems to have met a long-felt want, for the favorable reception accorded to the first edition has now necessitated the appearance of a second. The book opens with a historical introduction, following which the author considers in a most complete manner the legal and sociological aspects of this subject. He believes that the question is of such importance to national existence, that the government should take official cognizance of these conditions. In many cases his recommendations would not apply, as the desire to terminate a pregnancy during the early months is often based on reasons which cannot be governed by outside influences, but a great majority of these cases are to be found among a class who desire a limitation on account of their economic situation, or in those who have conceived out of wedlock and are prompted to resort to abortion from feelings of shame and fear of exposure. The author claims that some effect, however small at first, may be gained by the erection of a sufficient number of maternity hospitals, where women may be accommodated without exposure and their children taken care of. No doubt such asylums would be constantly filled and the number of illegitimate births markedly increased. But this, the writer claims, need not be considered as a sign of increasing immorality—it would only evidence the fact that a larger number of children had been allowed to come into the world that would otherwise have been destroyed *in utero*. The other sections of this interesting work are concerned with the dynamics of abortion and the pathology of fetal death. The various forms of abortion are also studied, both historically and ethnographically, and their universal distribution, in both past and present times, in almost every quarter of the globe, is astounding. Even the lowest types of savages resort to such measures. Considerable space is given to the subject of organic and inorganic abortifacients, and the mechanical means are also considered. The work is supplemented by an excellent index. An immense amount of painstaking research must have been devoted to gathering and arranging the large quantity of material presented.

Principes Fondamentaux d'Obstétrique, Vérifiés, Rectifiés ou Etablis à l'Aide de l'Expérimentation sur le Mannequin Naturel et de l'Observation sur la Parturiente. Introduction à l'Etude Clinique et à la Pratique des Accouchments, Anatomie, Présentations et Positions, Mécanisme, Toucher, Manœuvres, Extraction du Siège, Version, Forceps. Par le Professeur L. H. Farabeuf et le Docteur Henri Varnier. Préface du Professeur A. Pinard. Dessins démonstratifs de L.-H. F., donnant avec les répétitions nécessaires 362 Figures. Nouvelle Edition Revue et Corrigée. Paris: Georges Steinheil, 1904.

In looking through this valuable book with its numerous graphic illustrations, one cannot but wish that it had been in his hands in student days. The authors of this treatise have fully realized the special preparation necessary for the practical study of obstetrics. Pinard, who has written the preface, declares that the student who pretends to be able to profit by the teachings of the clinic without being prepared by theoretical studies and manual exercises, would be even worse off than one who would become a surgeon without knowledge of anatomy or of operative technique. He is convinced that the great difficulty of to-day, in teaching obstetrics, results from the fact that students do not have sufficient preparation for this branch of medicine. The illustrations, of great accuracy, are a most valuable feature of this work, which has been thoroughly revised, corrected, and brought up to date in every respect. It is a perfect guide to the study of obstetrics. The first chapter describes in detail the pelvic-genital canal. The second chapter deals with the fœtus, its presentations and positions, all of the cuts being taken directly from nature. Forty pages, containing forty illustrations, are devoted to the exposition of the mechanism of labor in its various phases. The consideration of diagnosis by touch, manual intervention in breech presentation, version, and forceps, follow in order. The basis of this work was a series of five years' experiences and manœuvers made with the supple bodies of women and fœtuses embalmed in glycerin. These experiments were controlled by clinical observations. As Pinard says, this book, the first of its kind, is indispensable to every student and practitioner who desires to follow successfully the line of obstetrics.

Lehrbuch der Speciellen Chirurgie. Von Dr. Franz König, in Berlin. Achte Auflage. I and II Bande. Berlin: Aug. Hirschwald, 1904.

This well-known work, by one of the foremost surgeons of Germany, is now appearing in its eighth edition. The esteem in which the work is held may be gauged by the necessity for so many successive editions. Although a considerable period of time has elapsed since its first appearance, the book is by no means old-fashioned. The expansion which the subject of surgery has undergone has necessitated the addition of a third volume, and as the magnitude of such a work is too great to be properly accomplished by one man, the author has enlisted the services of his son, Prof. Fritz König, as collaborator. There are no special points of departure from the editions which this one succeeds, and the present one presents merely an effort to keep the subject matter of the book up to date. Two volumes are now at hand, and the third is soon to follow. The special surgery of the head, chest, abdomen, and male genitals is thus far treated, the sections on the head and abdomen being very elaborate. The arrangement of contents and the typography are excellent, but what impresses the American most is the lamentable lack of good illustrations.

Golden Rules of Anæsthesia. By R. J. Probyn-Williams, M.D., Senior Anæsthetist, Etc., at the London Hospital. Bristol, Eng.: John Wright & Co., 1904.

In this small book, which may be readily carried about in the vest pocket, the author presents some of the principal points to which the attention of the student must be directed during the practical part of his course of instruction in the administration of anæsthetics. It will also serve a useful purpose to those practitioners who may be occasionally called upon to give an anæsthetic. The author's language is concise and his words well chosen, and the subject of general anæsthesia is quite fully summarized within the brief limits of sixty-five pages. The subject matter is in the form usually of pointed paragraphs, the majority of which are governed by the words do, don't, and remember.

Wurmfortsatzentzündung und Frauenleiden. Von Dr. Theo. Landau. Berlin: August Hirschwald, 1904.

The subject of appendicitis is no less interesting to the internist and the surgeon than it is to the gynecologist, especially if we include in the term gynecology, the study of the affections of all the abdominal organs in the female. On these grounds the author of this little work finds a good reason for presenting it under the above title. Within the limits of its eighty-two pages he discusses briefly the relations between appendicitis and gynecological affections, and gives particular attention to the diagnosis and treatment of appendical inflammations when these are combined with the latter. In commenting on the etiology, he finds as the results of his personal studies, that appendicitis *per se*, whether in the severe acute or the more chronic forms, attacks men more frequently than it does women, but that in the latter the inflammatory process usually approaches from without, rather than from within, *i.e.* periappendicitis. Although there may be some difficulty in recognizing appendicitis in either sex even when uncomplicated, a much greater uncertainty exists when, in a woman, the disease is connected with some inflammatory process in the pelvis. A detailed description of the differential diagnosis contains many practical suggestions which cannot be here abstracted. Therapeutic measures must always be directed against both diseased processes. The author advises early operation, especially when the case is seen within forty-eight hours; after that it may be advisable to wait, although ready to proceed to more radical measures at any moment. He prefers the transverse incision through skin and fascia, followed by a longitudinal one through muscle and peritoneum, to the smaller lateral incisions.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Sixteenth Annual Meeting at Detroit, Mich., May 30 and 31 and June 1.

AUGUSTUS CAILLÉ, M.D., PRESIDENT, IN THE CHAIR.

(Special Report to the MEDICAL RECORD.)

(Continued from page 394.)

Tuesday, May 31—Second Day.

Nervous Exhaustion in Infants.—Dr. WILLIAM P. NORTHRUP of New York reported some cases of nervous exhaustion occurring in young babies as the result of noisy surroundings and of too much petting at the hands of parents, grandparents, and friends to whom the wish was to "show off" the infant. He thought the society should interest itself in teaching the lesson of quiet surroundings and especially of allowing a certain quiet to initiate stomach digestion. He pointed to the necessity of close and constant watching and individual case studying. The coming generation should be protected from nervous exhaustion, nervous dyspepsia, sleepless nights, and choreic jerkings before they cut their first teeth.

Dr. AUGUSTUS CAILLÉ of New York said the hysterical doctor was, as a rule, a very popular man, and was to blame for many of the conditions Dr. Northrup criticised.

Dr. C. P. PUTNAM of Boston said he was always afraid of the so-called "good" nurses, who are so devoted to the children. By their devotion they kept the children awake

Dr. SAMUEL S. ADAMS of Washington, D. C., said that we should beware of the nurse who puts the child to sleep, and especially the very much over-rated Southern "mammies."

Dr. ROLAND G. FREEMAN of New York referred to the condition of nocturnal incontinence of urine which could be cured by taking the child away from the neurotic mother or nurse and placing the child under the care of a trained nurse. Many cases of constipation in infancy were due to the nervous environment. This could be easily remedied by placing the child in proper environment.

Address of the President.—Dr. AUGUSTUS CAILLÉ of New York delivered the presidential address, taking as his subject the influence of the American Pediatric Society in promoting the welfare of American children. After fifteen years of prosperous existence, he thought the time had come when this society should be ready to assume broader obligations and to grapple with larger problems, to promote and shape the public understanding regarding sanitation of the child's environment, and to supervise the education of the American child from a medical standpoint. He, therefore, asked permission to point out briefly some of the more important matters to which they, as a body, might direct their attention.

The Overheating of Homes and the Fear of Catching Cold.—This was a most fruitful source of ill health in children. The fear of breathing fresh air still held possession of the multitude, and the comparatively few physicians who dared to advocate the breathing of cool, fresh air were looked upon as little short of dangerous advisers by the wiseacre of the domestic hearth. The susceptibility to cold-catching could be markedly reduced by judicious bathing in connection with proper alimentation. In older children a hardening process by cold douching was undoubtedly beneficial and would strengthen the child's forces and permit it to overcome inclement influences of various kinds. This suceptibility to cold-catching could not, however, be reduced in homes in which overheating of the living apartments was tolerated. One of the most dangerous methods of heating a room he believed to be the portable gas stove not connected with a flue, because the products of combustion remained in the room and vitiated the air. Overheating and faulty heating should be condemned by the medical profession at every opportunity, and fresh air treatment of the healthy and sick children should be insisted upon. In Boston the wealthy and aristocratic families were putting their babies to sleep out of doors on roofs, balconies, and wide window-sills.

Disinfection and the Sanitary Code.—He said that the removal of the child to another apartment during the fumigation process theoretically and practically nullified all efforts to destroy the sources of infection and stamp out contagious diseases. The compulsory cleansing of an apartment with soap and water as practised in Germany had more real value than fumigation with sulphur. One of the principal means of the spread of infection could be found in the cloak-room of factories and schools. The same might be said of books in schools and libraries; they were frequently soiled with the nasal discharge of the sick. Compelling children who were convalescing from diphtheria to keep indoors until all bacilli had disappeared from the throat was unreasonable, because it deprived them of the tonic effects of fresh air which they required, and because the infectious nature of these bacilli found during and after convalescence had not been proved. He deprecated the taking away of children suffering from ordinary eruptive fevers and transferring them to suburban hospitals against the will of the parents. The fear that such a course would be pursued had prevented parents calling in a physician and had kept well-meaning and humane physicians from reporting cases. If the community demanded isolation of these cases the authorities should insist upon securing proper accommodations for mother as well as child.

School Hygiene and School Inspection.—Under the championship of Dr. Caillé, at a public meeting of the pediatric section of the New York Academy of Medicine, the daily medical inspection of the schools of the City of New York received its first practical agitation in 1890. It was successfully inaugurated in Boston in 1894, in New York in 1897, in Philadelphia in 1898. This inspection had primarily for its object the early detection of communicable diseases, but it should embrace the hygienic guardianship of school-children. Such inspection revealed unsanitary conditions in general existing in schools, day nurseries, and kindergartens; it was a powerful factor in promoting the cleanliness of the scholars, and insured proper attention to existing parasites, skin lesions, and obnoxious habits. Children with communicable diseases, mouth-breathers, backward and neurotic children, anæmic children, etc., were detected and put in the way of receiving the benefits of proper treatment. It was estimated that fully 90 per cent. of the curvatures not due to bone disease were developed during school life by faulty positions in sitting, while writing and studying, and in standing. The early detection of vaginal discharges of gonorrhœal origin was most important. When medical inspection was continued with rational elementary instruction in hygiene the best chances were offered for lessening sickness in school-children because teacher, parents, family physician, and inspectors coöperated.

School Fatigue and Backward Children.—In 1900, 16,000,000 children were enrolled in the common schools of this country. The opportunity for acquiring knowledge was the same for all school-children, but not all children had the same capacity. The relative endurance of the sexes varied; about one girl in twenty was obliged to give up her school life on account of ill health. The present-day native American girl of the middle class was the artificial product of advanced civilization; she was a bundle of nerves encased in a fragile frame. He believed the pediatrist should call a halt and demand for the children less brain gymnastics and more fresh air and exercise. Backward children should have separate class-rooms and special care. One of the duties of the physician, the statesman, and the teacher was to find out the weak spot, for these children had the same right to an education which would fit them for a sphere of usefulness that the blind had.

Bodily Training of Pupils and School Baths.—Inhibition to sit still was one of the first lessons of school life, but unnatural order should be dispensed with and the children should be allowed all the physical activity compatible with the best results. The time was coming when the playground would be as seriously considered as the school itself. The lesson of personal cleanliness was one of the fundamental principles of education. The shower-bath was the best and most sanitary for public schools and public bathing places, and probably was of more importance to the community than public libraries.

Infants' and Children's Hospitals.—He believed that medical opinion should discountenance the erection of large institutions in the city to be filled with chronic cases and minor ailments. They were adopted only for the acute cases. The country and seashore sanatoria and floating hospitals were not for the chronic cases. As soon as their condition permitted, the children should be sent home from the hospitals because, as the result of hospital life only, they lost color, appetite, and weight. For fighting house infection in the babies' ward of the Post-Graduate Hospital, the following regulations were drawn: (1) Strict cleanliness of premises and inmates; (2) thorough ventilation; (3) sufficient air space; (4) no overcrowding of wards; (5) infants are not to be fed by the same hand that attends to the toilet; (6) soiled linen is to be immediately removed and disinfected; (7) feeble children are toned up by a change of air, such as a trip to Staten Island or an omnibus ride through the park, and sojourn in the sunbeam play-room and roof garden.

Educational Features in Pediatrics.—Undergraduate teaching might be carried out by means of didactic lectures and bedside instruction; post-graduate teaching should be systematized on a strictly clinical basis; and physical diagnosis, laboratory work, and dietotherapy and hydrotherapy shall be made a prominent feature in the course of pediatrics. In giving clinical instruction in pediatrics, Dr. Caillé during the past fifteen years had adopted the following plan: The first forty minutes of the clinic were devoted to a more or less rapid demonstration of ten or fifteen sick children who were placed on tables accessible to the matriculates, the balance of the hour being taken up by a discussion of the principles of treatment of important groups of disease, or a demonstration was given of stomach washing, bowel irrigation, spinal puncture, intubation, tracheotomy, or other operation.

In conclusion Dr. Caillé suggested that the annual transactions should contain a running record of the world's progress in pediatrics by presenting at each meeting a critical review of it during the year under the following headings: (1) Home School and Hospital Hygiene and Prophylaxis. (2) Teaching Methods in Pediatrics. (3) Diagnosis: Bacteriological, Chemical, and Regional. (4) General Therapeutics, including Nutrition, Diet, Hydrotherapy, Phototherapy, Electrotherapy. (5) Surgical Therapeutics, Orthopedics, and Mechanotherapy. At each annual meeting the council should designate the members who would be expected to furnish a critical review of progress for the next annual meeting, thus giving them a year's time in which to collect material.

Analysis of One Hundred and Eighteen Cases of Lobar Pneumonia in Infancy.—Dr. John Lovett Morse of Boston read this paper and gave the following summary: Lobar pneumonia is more common and occurs relatively more frequently in comparison with bronchopneumonia in infancy than is generally supposed. The analysis of these cases shows the following points: The onset was less stormy than was generally supposed. It was often ushered in by vomiting, but rarely by a convulsion. It usually began with fever and cough, which were often accompanied by apathy or drowsiness. Movement of the alæ nasi was not a constant symptom. A whole lobe was more often involved than a part. The left lower lobe was the one most frequently involved. The right upper and right lower lobe came next in frequency. The portion of the lungs involved was relatively the same in the fatal cases as in those which recovered. As a rule, the area involved was larger in the fatal cases. The average duration of the fever in the cases that recovered was about eight days, being nearly the same in both years. The course was more often short in the first year, however, than in the second. The average duration of the fever in the uncomplicated cases that were fatal was 12.8 days; that is, the duration of the fever was longer in the fatal cases than in those that recovered. The highest temperature was usually between 103°F. and 106°F., the number of cases being nearly the same for each degree. The temperature fell by crisis in 68.8 per cent. Crisis was less common in the first than in the second year. Collapse during the crisis was very unusual. Pseudo-crisis were not very common, but irregularities and remissions in the temperature were not at all unusual. The mortality was lowest when the temperature did not rise above 103°F., and highest in those cases in which it went over 106°F. The degree of fever between 103°F. and 106°F. had no apparent effect on the mortality. A high temperature was no more fatal in the second year than in the first year. The usual pulse rate was between 150 and 170. No case died in which the pulse was not over 140. The rate of the pulse, when it was above 140, had little or no apparent effect on the mortality. The usual respiratory rate was between 55 and 80. No patient died whose respirations were below 55. The rate of the respiration, when above 55, had no apparent effect on the mortality. The mortality, excluding the cases in which death was due to empyema, was nearly 23 per cent. It was almost twice as great in the first as in the second years, being 32 per cent. and 18 per cent. respectively. Otitis media was the most common complication, occurring in 18 per cent. Empyema was the next most frequent, occurring in about 8 per cent.

The prognosis of lobar pneumonia in infancy varied decidedly with the age of the patient and to a certain extent with the amount of lung involved. The prognosis was good when the temperature was not over 103°F. It was serious when it was above 106°F. Variations between these points made little or no difference in the prognosis. The prognosis was good when the pulse was not over 140 or the respirations over 55. The amount of the increase above these limits was of little importance.

Dr. Charles G. Kerley of New York said he was surprised at the variations of pulse and respiration in healthy, normal children.

Dr. F. S. Churchill of Chicago said that he had no doubt that lobar pneumonia existed more often in children than was generally supposed, and he believed this was due to the fact of careless examinations. He related the instance of a baby two months old who contracted a pneumonia and the culture showed the pneumococcus and the smear the bacillus of influenza; the child recovered from this attack. Six weeks later another lobar pneumonia developed in exactly the same spot and, in the course of ten or twelve days, the child died. The culture here showed only the pneumococcus but no influenza bacillus was found. It was interesting that with the combined infection the attack was trivial. The combination of these two in an adult was usually fatal. Regarding the treatment the giving of the depressing antipyretics in infants was far more dangerous than in adults. Sponge baths were better borne than tubbing.

Dr. L. E. Holt of New York said that in a series of sixteen cases he had found the left lower lobe affected alone. With regard to prognosis it seemed to him that when but one lobe was involved it was rarely fatal, no matter where the temperature and pulse and respirations went, provided the child was in fairly good condition previous to the onset of the disease. He believed that

too much importance was attached to the rapidity of the pulse; it was the quality and not the rapidity of the pulse that was so important. He could recall a child with a temperature of 107.7°F. who recovered. The antipyretic treatment of pneumonia, he confessed, was a failure. The element of rest should not be forgotten.

Dr. Samuel S. Adams of Washington, D. C. believed that the mortality quoted was altogether too great, for it did not accord at all with his experience. Ten per cent. was about his mortality in private practice He had long since abandoned baths except in extreme cases. If a patient had a temperature of 108.6° he would advise clearing out the bowels and placing the child in the tub; in one such case he found that, two hours afterwards, the temperature had dropped to 104° but the lung was solid from base to apex and the child was moribund.

Dr. W. P. Northrup of New York prophesied that two years from now these cases of pneumonia would be treated by placing the patient near a window where he could get much cool, fresh, wholesome air, which would not only act as a stimulant but as an antipyretic.

Dr. Morse in closing the discussion said that the pulse and respirations were taken when the children were asleep or quiet and by rectum. The point he wished to bring out particularly in his paper was that there was no particular cause for alarm if the pulse and respirations were rapid. He also wished to bring out in his paper the fact that lobar pneumonia in infants was a more serious disease than generally supposed.

Acute Pyelitis of Infancy.—Dr. Rowland G. Freeman of New York read this paper. He said that any disease which could pass unrecognized while under intelligent observation for several weeks, on account of the absence of local symptoms pointing to the location of the disease, deserved to be called frequently to the attention of the profession in order that the characteristics of its manifestations might become familiar and subsequent cases not be overlooked. Acute pyelitis of infancy was a disease of this sort. Its rarity was sufficiently emphasized by the small number of cases reported. The etiology of most of the cases recorded was very indefinite. A very large proportion of them occurring in female children, and infection from the genitourinary tract seemed probable, while the organism associated with most of them, the bacilli coli communis, pointed to an infection from the alimentary tract, as did the fact that many of these cases followed intestinal disorders. The clinical manifestations gave no evidence that the pelvis of the kidney was the source of the trouble. These patients usually had abnormal movements from the bowels associated with a high temperature of irregular type with marked remissions and followed by a rapid elevation, which in some cases was accompanied by chills. The procuring of a specimen of urine from a baby involved some difficulty for those unaccustomed to work with these little ones, so that this method of diagnosis was apt to be neglected. On this account he believed that many of the recorded cases had been allowed to progress for long periods of time before curative treatment had been adopted. This was very unfortunate because curative treatment was simple and safe, consisting in neutralization of the urine. A case was then reported which seemed of interest since it occurred in a male child; questioning the mother revealed the fact that the infant showed some evidences of urethral irritation at the beginning of the attack, which attack was preceeded by two or three weeks of slight digestive disturbance as indicated by abnormal stools. The child continued sick for three weeks with an irregular temperature which towards the end of this period remained constantly very high and was associated with such nervous symptoms as twitchings and stiffness of the back of the neck. As soon as remedial treatment was instituted on the twenty-second day of the disease, the temperature steadily declined until it reached normal on the twenty-ninth day. The child had steadily gained in weight and became perfectly healthy. A detailed history of this case with the results of the blood examination here followed.

Dr. J. Lovett Morse of Boston thought that the frequency with which this condition was met depended upon how frequently we examined the urine. In Boston for several years an examination of the babies' urine had become a routine practice and he had never gone on service in the hospital without finding from two to four cases of acute pyelitis in the wards. Diagnosis was rather difficult, even though the urine was carefully examined; babies might have an acid urine and a great deal of pus but nothing else, and it was hard to tell whether the pus came from the kidney or the bladder. In cases in which he found squamous cells he supposed the trouble was in the bladder; when he found spindle and caudate cells then he believed the kidney to be the seat of the trouble, this leaving either a pyelitis or a pyelonephritis. Nearly all such cases he thought to be due to the colon bacillus, but this was a new subject and the field was open for further investigation. In two cases that he had seen the presence of tubercle bacilli in the urine opened up another new field for him. In these cases there was tuberculosis of the kidneys but no tuberculosis elsewhere. He had found no difficulty in obtaining urine from babies for examination.

Dr. Isaac A. Abt of Chicago said that some years ago he had speculated regarding the cause of this infection and in a large number of cases, twenty-six or more, the infection appeared to come from some part of the bowel, particularly a follicular enteritis. He then wondered if the colon bacillus could go through the lose cellular tissue of the pelvis. It seemed to him there must be some more direct mode of infection through the vascular system or the lymphatic system. He reported an instance of acute pyelitis in which the Shiga bacillus was found in the urine and this again opened up a new field for investigation, as to whether or not the Shiga bacillus could be found in the urine.

Dr. Thomas M. Rotch of Boston spoke of the great difficulty of discovering the tubercle bacilli. In the cases that he had seen he had found the disease to be exceedingly latent and the tubercle bacilli would not have been found if repeated examinations had not been made.

Dr. John Dorning of New York thought that the society could not too strongly emphasize the importance of urine examinations in children's diseases. Years ago Dr. Jacobi had exhibited a small catheter (No. 5) in two sections, the operator had carried one of these in his pocket for years and usually demonstrated its use at the clinic. An instrument maker in New York made four or five hundred of them and sold all, so that they must now be scattered all over the country. The diagnosis of acute pyelitis in children he had found to be rather difficult on account of the vague symptoms. When there was frequency in urination and distress at the neck of the bladder he then looked for this condition in children. He believed one should always suspect a tuberculous condition in cases of pyelitis. The condition was a very latent one and often even the microscopical examination did not aid in making the diagnosis and even the inoculation of guinea-pigs may not aid.

Dr. Floyd M. Crandall of New York asked regarding the possibility of increased susceptibility to kidney trouble in later years after children have suffered attacks of acute pyelitis.

Dr. L. E. Holt of New York said he had patients under observation, one for ten years, the other for nine years, and they were absolutely well and the attacks they had were very severe.

Dr. A. Jacobi said that a more lasting impression was made on medical men if certain things were hammered and hammered again into them, and one of the things

that should be frequently hammered was that when one had a doubtful case and a diagnosis had not been made, the urine should be examined and often one would be rewarded by finding evidences of acute pyelitis. If there were pus and bladder epithelia in the urine it was reasonable to suppose at least part of this came from the bladder; but if there were present in the urine renal epithelia and now and then small granular cast, and possibly later some blood and pus, that would indicate pyelitis. In cases of pyelonephritis there were more kidney elements than in cases of simple pyelitis. He had frequently been called to see cases of protracted fever that had been unfortunately diagnosed as malaria and found a case of nephritis or pyelitis. It was not sufficiently hammered into the heads of medical men that nephritis was a frequent disease in young infants; the urine should be more often examined. There was one remedy he was very fond of and that was gallic (not tannic) acid in large doses; it was an agent well tolerated. Regarding tuberculosis he had not seen many cases, and it was exceedingly difficult to find the tubercle bacilli in the urine. He believed that cases resulting from bacterial infection would get well; but if they were the result of calculus then the prognosis was graver.

Dr. Freeman said that at the Foundling Asylum in New York the urine of children was examined regularly, and no difficulty was experienced in obtaining samples of urine from babies.

Acute Myocardial Insufficiency in Some Infections in Children.—Dr. F. Forchheimer of Cincinnati read this paper. He said the importance of this subject lay in the fact that a large number of these acute myocardial insufficiencies developed in connection with the infections in childhood and, beyond the possibility of a fatal termination from this acute condition there remained another which was far reaching for the future of the individual who survived. In some of these cases the myocardial changes were so marked that permanent damage was done to the heart, which might only manifest itself when an extraordinary call was made upon the functional activity of the heart. As it was a fact now accepted by all that in every case of pericarditis and endocarditis the myocardium was more or less involved, it could be seen how great the number of cases became in which it was possible that acute myocardial insufficiency might develop. The development of symptoms of acute myocardial insufficiency depended upon the amount of damage done to the myocardium. At first there was noticed a diminution in heart force and arrhythmia; then followed dilatation of the left heart, then of the right heart, with relative insufficiencies of their valves; so soon as the right heart was seriously affected, then followed marked enlargement of the liver. The latter he had seen descend to the level of the umbilicus. The signs and symptoms varied in different diseases, but, upon the whole, there were weakness, irregularity of the pulse and heart impulse, tachycardia or bradycardia, a broadening of the heart dulness, and bruits heard most commonly over the apex, the mitral and the tricuspid areas, but frequently also over the base. To this class belonged the two cases referred to in his contribution to Jacobi's "Festschrift." Diphtheria, of all the acute infections, most frequently produced myocardial insufficiency, which most common during the second and third week. Too much stress could not be laid upon the fact that pure myocarditis was not the only cause that produced heart death in diphtheria, for there were at least two other processes that complicated it. The first was the effect of the diphtheria toxin upon the cerebral vasomotor centers, causing a dilatation of the blood-vessels, and therefore the blood was not properly propelled. The result was the heart simply "bled itself" into the splanchnic area, and, after a time, very little blood flowed into the right heart. The second method of complicating the clinical course was an affection of the vagus. It had been thoroughly established that, in diphtheria, the vagus was frequently affected, and it had been established that in a large number of infectious diseases there was arrhythmia. Diphtheria arrhythmia was due to disturbance of the vagus. Next to diphtheria, his experience with myocardial insufficiency had been with septicæmia of influenza. All the cases he had seen had been accompanied by more or less cardiac change, and the worst case in children that had come under his observation and which recovered he reported in detail.

In the treatment of uncomplicated myocardial insufficiency, the first principle was absolute rest. The digitalis group of drugs might be used, their efficacy depending upon the amount of myocardium affected. Predisposing causes should be controlled. According to the severity of the case stimulants will be demanded. Convalescence should be carefully guarded, and for the purpose of strengthening the myocardium mechanical means were invaluable. Laxatives that acted too violently should be avoided. Strychnine might be used for its general tonic effects; except in toxic doses it had no effect upon the heart nor upon the vasomotors. Nitroglycerin should never be used, unless there be angina attacks. His own method, which had been productive of good in two cases, was as follows: Hypodermic injections of adrenal extract repeated every two hours; saline transfusions in the beginning, in order to keep up the heart's contractions; ice-bags upon the abdomen, stimulating the splanchnic reflex. In one child he was able to bring down the pulse from 140 to 60 by the use of these alone. After the most violent symptoms had passed over, then caffeine and sodium salicylate were given every two hours, alternating with the adrenal extract, which was gradually dropped.

Dr. Thomas M. Rotch of Boston said that all had cases of acute dilatation of the heart which lasted but a short time, and these cases should be treated with absolute rest, as advocated. He thought the great importance of the paper just read was in drawing attention to certain points which the general practitioner did not, as a rule, recognize.

Dr. A. Jacobi of New York said that only during the last twenty or twenty-five years had much attention been paid to the myocardium, and only during the last ten or twelve years had the profession awakened to the necessity of studying the myocardium and its diseases more. Now we knew that we could have a pericarditis, an endocarditis, and a myocarditis at one and the same time. It was Engelman of Boston and others that had shown the importance of the heart muscle removed from the influence of the nervous system, and since then more or less attention had been paid to it and its changes. There were two forms of myocarditis, the simple parenchymatous degeneration and the real interstitial inflammation. Now and then one came in contact with an old cicatricial condition more or less extensive. The parenchymatous degeneration showed itself in different ways. In pneumonia the particular danger was not so much during the acute stage, but when the crisis came; then all at once the temperature fell, the pulse fell and became irregular, and sometimes collapse and death occurred. Toxins must have developed in the course of the disease which gave rise to the particular heart symptoms

With regard to treatment, there was nothing he avoided or disliked more in acute myocarditis than digitalis, which caused contractions, not only of the heart but also of the arteries. The labor placed upon the heart after fair doses of digitalis he considered to be too great, and the same remark applied to strychnine. He relied more upon cold applications to the heart, such as ice-bags for a short time, and opiates, especially codeine. He also liked the iodides. Absolute rest was to be enforced, especially rest in bed.

Dr. F. Forchheimer said the object of his paper was to attempt to establish some form of treatment in myocardial insufficiency, in both the acute and chronic cases. He

presented two clinical pictures, one a myocardial insufficiency due to a pure and simple myocarditis, the other as a complication. In treating myocarditis he said he never would think of using digitalis, but would insist upon rest, and particularly rest in bed.

Wednesday, June 1—Third Day.

Asthma in Infants and Children, with an Analysis of Forty-three Cases.—Dr. L. E. La Fetra read this paper. Eleven cases occurred during the first year of life (8 males and 3 females). Eight cases occurred during the second year of life (6 males and 2 females). Nine cases occurred from two to five years (8 males and 1 female). Fifteen cases occurred from five to twelve years (10 males and 5 females). The nationality of the patient was given as follows: United States, 16; German, 8; Swedish, 2; Dutch, 1; Irish, 6; United States (colored), 2; Hebrew, 9. It seemed to him remarkable that no Italians and only two negroes were in this list, because one would expect rickets to be an important predisposing factor, as it was in cases of spasmodic croup and bronchitis. At the time the patients came under treatment the disease had existed less than 3 months in 9 cases, from 3 to 6 months in 5 cases, from 6 to 12 months in 4 cases, from 1 to 3 years in 9 cases, from 3 to 6 years in 5 cases, and over 6 years in 3 cases. The family history was asthmatic, rheumatic, tuberculous, or neurotic in many cases, but the answers were not reliable enough to be suitable for statistical purposes.

Abnormalities of development were marked in several cases, especially when the symptoms began at birth or during the first year of life. There was pulmonary atelectasis in 2 cases, an enlarged thymus gland in 2 cases, pigeon-breast in 1 case. Two of the children were prematurely born, and one was of the Mongolian type of idiocy. Twenty had previously suffered from bronchitis; 7 had had bronchopneumonia. Altogether 27 out of 43 patients had had some pulmonary inflammation preceding the attack of asthma. Rickets were present in 8 cases. One patient had suffered from chorea. The cause of the attack was: In 14 bronchitis, in 1 bronchopneumonia, in 2 pneumonia, and in 1 each gastric indigestion, a drive against a cold wind, a fall, and an attack of malaria. In 8 cases the attacks occurred daily or with no stated intermissions; in the others the periods varied from two weeks to "every winter" or "every summer." The attacks were worse by day in only 2 cases. Three cases only were distinctly worse during the hot weather. Emphysema was associated with asthma in 6 boys and 4 girls; 5 of these had the square or barrel chest. Emphysema with bronchitis was present in 2 girls and 3 boys, and only one of these had a barrel chest. Abnormalities of the nasopharynx were associated as follows: Congenitally high arched palate (without adenoids) in 1 case; deflected septum in 2 cases; adenoids and enlarged tonsils in 20 cases. Nearly one-half these cases suffered from adenoid growths, and this was quite a significant fact. The usual symptoms of asthma were present. The leucocytes were usually increased. A differential count showed a constant and usually marked increase in the number of eosinophiles. The differential count of leucocytes he considered to be of diagnostic as well as prognostic value. If it was kept in mind that asthma did occur in infants and children there would be encountered few difficulties in making a diagnosis. The presence of an increased number of eosinophiles, together with speedy recovery and with recurrences, would confirm the diagnosis.

Speaking of pathogenesis, he said that the peculiar type of breathing was induced by a narrowing of the lumen of the bronchial tubes, but the cause of this had been productive of much discussion, two theories being favored, viz., spasm of the smooth muscle fibers of the smaller and medium-sized bronchial tubes, and vasomotor tumefaction or paresis, a sort of angioneurotic œdema or urticaria of the bronchial mucous membrane. This theory was supported not only by experimental evidence but by analogy and the results of certain forms of treatment.

A careful study of the patient's history and physical signs would suggest in almost all cases a rational and successful line of treatment. Predisposing and exciting causes should be removed. The attacks were to be treated on the basis of their pathogenesis. The general condition should be toned up by hygienic and dietetic measures. Bronchitis, adenoids, nasopharyngitis, etc., were all predisposing factors and should demand attention. The prevention of colds involved the whole hygiene of the child and should be attended to by daily sponge bathing, exercise in the open air, proper ventilation of the nursery day and night, etc. Adenoids and enlarged tonsils should be removed. Hypertrophic rhinitis, polypi, deflected septa, etc., should receive due attention. The toilet of the nose, as suggested by Jacobi, should be practised. In cases of long standing and for subacute cases he believed that nothing took the place of iodide of potassium. In infants, when the attack closely resembles capillary bronchitis, steam inhaled after being impregnated with creosote was very satisfactory in relaxing the spasm. In older children stramonium papers or nitrite papers, alone or in combination, were of value. So soon as the infant could swallow, tartar emetic and ipecac should be given along with some nitroglycerin; this he believed to be particularly efficacious when the attack resembled a bronchitis of the finer tubes. Another plan he had adopted with success had been the giving of atropine until the face flushed. If the attack was accompanied by gastric indigestion the stomach should be at once emptied, preferably by syrup of ipecac. In long-standing cases, and in older children, the old emphysema mixture gave good results in his hands, *i.e.* the mixture containing morphine sulphate, belladonna, and compound spirit of ether. On the theory that the attack was due to vasomotor paresis vasoconstrictors should be given. He had used suprarenal preparation with marked benefit in some cases.

Dyspnœa—Central, Peripheral, and Obstructive.—Dr. W. P. Northrup of New York read this paper. He said that every intubationist was interested in the different varieties of dyspnœa, and he wished to call attention to some unusual types. The first type was dyspnœa of peripheral origin, neuritis presumably diphtheritic, and paralysis of the diaphragm. The second type was dyspnœa of central origin, infectious transverse myelitis and paralysis of the thoracic muscles of respiration. The third type was obstructive and not of the nasopharynx, nor yet of the larynx, but due to accidental presence of air in the thorax, probably due to faulty exploration by needle.

Dr. Charles G. Jennings of Detroit said that he had reported a very interesting case at the Boston meeting of the society; the case was one of autointoxication with clinical manifestations appearing first at attacks of coma; the clinical picture soon changed, and instead of the condition manifesting itself as coma, asthma set in.

Dr. L. E. Holt of New York said that these attacks in children of six or eight years of age were very pitiable, and the only thing to be depended upon was a change of climate. He had always believed that if a child was not relieved of the asthmatic attacks before the age of ten or twelve he would become an habitual sufferer. He advocated improving the general nutrition of these patients by giving iron and cod-liver oil, particularly during the winter and spring, and keeping them as much in the open air as possible. These attacks were very likely to follow whooping-cough or measles.

Dr. Floyd M. Crandall of New York said that all knew how hopeless and how serious these cases were when they had gained any headway, and, therefore, if anything was to be done for them it should be done early, particularly after measles.

Dr. Isaac A. Abt of Chicago spoke of the dangers of

aspirating the chest by the unskilled. He had frequently noticed hospital internes poke the needle between the ribs, and they were taught that no harm could be done if only the needle was clean.

Dr. Augustus Caillé of New York has seen pneumothorax occur twice after puncture of the chest, and it was due to too expensive lateral excursions with the needle. With regard to asthma he recalled the time he was the guest of Dr. Dunbar of Hamburg, and he was shown an interesting experiment. The doctor was a hay-fever sufferer. He took the pollen poison in solution and instilled the eyes of both his own and Dr. Caillé's. It did not affect the latter, but, in a few minutes, Dr. Dunbar's became blood red. He then took the antitoxin (pollantin) and introduced it into the eye, and within half an hour all evidence of vasomotor disturbance had disappeared.

Dr. W. P. Northrup of New York said that the people should not be permitted to talk about "outgrowing" asthma.

Acute Leukæmia.—Dr. F. S. Churchill of Chicago read this paper. He said that nothing seemed to have a predisposing cause unless possibly tonsillitis, and the changes there might be the result rather than the cause. No age was exempt. The onset might be sudden, but often was insidious. The general course of the disease in children was practically the same as in adults. The spleen was enlarged in all cases, and it was not an infrequent phenomenon to see a diminution in the size of the spleen just prior to death. The duration of the disease was from four and a half days to five months. The chief interest centered in the blood examination. There was a diminution in the number of erythrocytes, and in the hæmoglobin. The number of leucocytes varied from 6,000 to 810,000. A falling white count showed approaching death. Age had no effect upon the total white count. The polymorphonuclears were reduced to a remarkable degree; myelocytes were extremely rare. The tendency was for the blood to turn to the fatal type. In twenty-nine cases there was but one in which hemorrhages occurred. Leukæmia presented a picture of a turning upside down of the blood count. The differential count was the only way in which to make an accurate diagnosis. The effect of intercurrent diseases seemed almost always to show a fall in the leucocytes. The results of autopsy threw but little light upon the problem. The bone marrow might be involved alone, but it was always involved. The authorities claimed that no case of leukæmia existed without involvement of the bone marrow, and therefore all cases were myelogenous in type. Bacterial examination was of no value; no specific organisms caused the affection. Any organisms that were found were simply invaders, and possibly entered by way of the tonsils. He referred to Nicoll's classification into three groups, viz., toxic, infectious and neoplastic, or cancerous. The true nature of leukæmia was unknown, and the treatment was of no avail. The spray had been tried without success in the belief that the disease might be malignant in nature. In such an obscure and fatal disease he believed that any treatment was justifiable, and serum injections seemed to offer the greatest hope of cure. The disease was probably more common than generally supposed. Prior to 1898, only seven cases had been recorded; since that date twenty-two had been recorded.

Primary Sarcoma of the Liver.—Dr. L. Emmett Holt of New York reported an instance of adenosarcoma of the liver occurring in an infant. Examination revealed a rather poorly nourished child, and on the right side of the abdomen a large tumor could be felt which extended beyond the umbilicus and down into the pelvis, filling the entire half of the abdomen. The surface of the tumor was smooth, and the outlines distinct. It was soft to the touch. Examination of other organs was negative. The temperature ran between 100° and 102°. The supposition that it might be an abscess of the liver led to a puncture of that organ, and the withdrawal of a bloody fluid, fatty droplets, and liver cells, but no pus The hæmoglobin was 55 per cent., and there were 17,000 leucocytes, but no differential count was made. The surgeon who was called thought that an incision was indicated, and, under cocaine anæsthesia, this was done. The finger passed into a mass of broken down material. A drainage tube was inserted, and the wound dressed. Two weeks later the patient died of exhaustion. At the autopsy the liver measured 19 cm. long, and 21 cm. wide, and weighed 735 grams. It was of light brown color, and projected 2 cm. above the liver surface. There was no peritonitis or thickening to be noted. There was a pericarditis, and also a bronchopneumonia, but no metastases were found. The microscopical examination showed adenoma with sarcomatous degeneration in the center. Only two other such cases had been reported in children The presence of a distinct capsule around the neoplasm seemed to argue in favor of the adenoma being the original process to which the sarcoma was added at a later date.

Radiograph of a Thoraco-Abdominopagus.—Dr. Samuel S. Adams of Washington, D. C., presented the radiograph of a monster of this nature which had come under the observation of Dr. H. B. Sheffield.

Officers.—The annual election resulted as follows: *President*, Dr. Charles G. Jennings, Detroit; *First Vice-President*, Dr. Charles G. Kerley, New York; *Second Vice-President*, Dr. J. Park West, Bellaire, Ohio; *Secretary*, Dr. Samuel S. Adams, Washington; *Treasurer*, Dr. J. Park West, Bellaire, Ohio; *Recorder and Auditor*, Dr L. E. La Fetra, New York.

Chicago Surgical Society.

At the May meeting Dr. Nicholas Senn reported a case of extensive carcinoma involving the left cheek, in the center of which was a perforation which communicated with the cavity of the mouth. Acting upon the supposition that it might be a case of abscess, he resorted, first, to curettage, hoping to improve the local condition as well as giving an opportunity to make an early diagnosis by the aid of the microscope. Sections under the microscope showed it to be a case of unusually malignant form of carcinoma that had its starting-point somewhere about the alveolar process on the left side, involved the entire cheek, and gave rise to extensive destruction. There was extensive regional dissemination, although the disease had lasted only three months. A radical operation was resorted to. The entire cheek was removed, leaving the angle of the mouth, and a small portion of the cutaneous covering of the cheek. He sacrificed the periosteal covering of the lower jaw on the corresponding side, and made regional dissection by removing the submaxillary gland with the chain of lymphatics as a preliminary to excision of the cheek, and covered the enormous defect which was produced by a plastic operation, using Thiersch's skin grafts. The wound healed by primary intention throughout. Dr. Senn reported a case of tuberculosis of the ribs, of a most pronounced type, in a man of forty years of age. Three large tuberculous abscesses involved the left side of the chest. One of these ruptured spontaneously, and a fistulous opening communicated near the nipple with a very large abscess cavity. Another abscess was found at the junction of the ribs with the cartilage near the sternum, and another to the left of the mammary line. The third, fourth, and fifth ribs were the seat of tuberculosis. The first abscess was the result of tuberculous perichondritis. The focus of tuberculosis of the fourth rib was almost directly over the pericardium close to the nipple. The third abscess was a little to the left, and involved the fifth rib. The ribs were resected in their entirety, necessitating an extensive operation. Dr. Senn had encountered three cases in two weeks of cysts of the ductus thyroglos-

sus. The patients were all young subjects, eighteen to twenty-five years of age, two females and one male. The cysts were comparatively small. The largest one was about the size of a small walnut. They were located in the median line between the thyroid cartilage and the base of the hyoid bone. The enlargement was slow, accompanied with pain and swelling. The skin was movable over the surface of the swelling in all of the cases. Fluctuation was distinct. Complete excision was resorted to. The cyst wall in one of the cases was as thin as tissue paper. In the last ten days Dr. Senn said he had encountered two cases of fibroma of the periosteum. In the first case the fibroma had its starting-point from the periosteum of the second rib close to the cartilage. The tumor extended over the surrounding bony framework in mushroom-like manner, and underneath the clavicle. The tumor was removed through a curved incision, with its convexity directed upward, and the flap reflected as far as the clavicle, thus laying bare freely the base of the tumor, which he found intimately attached to the periosteum of the second rib near the sternum. The tumor was very firm and smooth, and on making a section it cut almost like cartilage. He removed a second fibroma of the ribs last Friday from a woman thirty years of age, which was situated at the lower part of the scapula. The patient first noticed the tumor eighteen years ago. It became stationary, but later gave rise to serious functional disturbance by fixation of the arm. The tumor was removed. Dr. Senn exhibited two specimens from the face of a woman, seventy-one years of age, the subject of multiple senile warts. In both cases the disease involved the malar prominence on both sides. There were a number of these warts scattered all over the face, those over the malar eminence being the seat of repeated irritations, and had undergone transformation into epithelioma Valuable as the *x*-ray was as a diagnostic resource, Dr. Senn said, occasionally it leads physicians into difficulties. He related a case briefly in confirmation of the correctness of this assertion. The patient was a colleague upon whom he had operated twice before, once for a diffuse septic inflammation involving the right arm and forearm, and a second time for appendicitis. For a number of months he had complained of a vague pain in the right shoulder. The patient regarded it as a rheumatic affection. Local and general treatment failed to give relief. The pain increased in severity, and the shoulder-joint almost completely lost its function. Dr. Senn could find no indication of any swelling, but found at a point corresponding to about the middle of the base of the deltoid a limited area of tenderness. The *x*-ray picture showed in the center of the deltoid muscle a dark elongated spot. The shoulder-joint itself was normal. He thought he would make no mistake if he considered the case on the face of the photograph one of myositis ossificans. He thought the dark island represented bone tissue in the deltoid, as it appeared entirely separated from the greater tuberosity of the humerus. Upon this supposition he acted. He laid the deltoid muscle bare by a curved incision, reflected the flap upward, and found the deltoid absolutely normal. In palpating the deltoid he found at a point corresponding to the outer side of the bicipital groove of the greater tuberosity a hard swelling. He separated the deltoid vertically by the use of a director and came down to a hard mass, not bone, but underneath the periosteum it appeared to be encapsulated. He incised and exposed a large mass of inorganic salt-sodium bi-urate. Dr. Senn also reported two cases of lipoma arborescens. He also exhibited the new army splint devised by Howard W. Beale, and a combined stretcher and splint devised by Professor Stokes.

Dr. Leonard Freeman of Denver, Colo., read a paper by invitation, on "The Union of Ununited Fractures of the Neck of the Femur by Open Operation." He went at length into the literature of this subject, after which he reported a case of his own in a heavy, muscular man, thirty-two years of age, who had injured the right hip by falling on it in 1903. Operation was performed on October 10, 1903, about five months after the injury. Anterior longitudinal incision was made external to the sartorius, through which the neck of the femur was readily exposed, and a fracture located near the end of the bone. With difficulty a mass of tough fibrous tissue was snipped with scissors, between the ends of the fragments, which were freshened on each side of the gap with a chisel. A small incision was then made over the trochanter externally, and a hole for the reception of the screw drilled through the base of the trochanter, the external fragment of the neck, and into the head of the bone. The drilling proved to be a mere form, for the bones were so soft that the blunt screw could have been pushed directly through it without the boring of a preliminary hole. When the screw was in place, its outer end projected between the stitches used in closing the wound. Owing to the softness of the bone, the parts, although receiving considerable support, were far from being firmly held, so that it was possible to displace them with moderate force by rotating the limb or pushing it upward. On account of oozing, it was necessary to pack the wound with a strip of gauze, which was removed in a day or two, the opening closed, and primary union obtained. Extension, a long side splint, and a pad beneath the trochanter were employed. For several days the suffering was great, necessitating the constant use of morphine. In a week or so a little infection appeared about the opening, through which projected the screw, which at the end of about two weeks caused a rise in temperature to nearly 100°, accompanied by chills and much general disturbance. On removal of the screw these unfavorable symptoms promptly subsided, showing that they were probably due to infection of the cancellous structure rather than the joint. The subsequent recovery was rapid and uninterrupted. There was about one inch shortening. In the face of various tests, the union seemed to be sound and bony. He examined the patient again, a little over six months after the operation, and found the following condition: Union apparently firm, considerable callus, flexion to nearly a right angle, rotation almost normal, and about one and a half inch shortening. There was still enough pain in the joint anteriorly to prevent the patient discarding his crutches, although it was much less than before the operation, and was decreasing constantly. When not attempting to walk, the weight could be borne upon the limb with but little, if any, discomfort. Up to the present time the case had not been a complete success, the result being marked improvement only. What the ultimate outcome would be was yet to be ascertained. Dr. Senn questioned whether Dr. Freeman had reached an ideal result in his case. In the years 1882 and 1883 the speaker studied this question scientifically. Up to that time it was doubted whether union by bone under any circumstances could be obtained in cases of intracapsular fracture of the neck or femur. He produced this fracture on the lower animals by drilling the neck of the femur in different directions and fracturing it, satisfying himself in each instance that he had produced a fracture inside the capsule. He treated twenty-three of the animals thus experimented upon by the methods then in vogue, but in all of these twenty-three cases he failed. He then resorted to direct methods of fixation. Breaking the bone in a similar manner, he made use of ivory bone pegs and metallic nails. In ten experiments following the twenty-three failures he demonstrated that he had obtained bony union in nearly all of them. He found afterward that the same results in the human subject were obtainable by indirect methods of fixation by bringing the fractured surfaces in contact and holding them in apposition by lateral pressure by a splint of his own device. He had treated since that time fifteen or twenty cases, and in the majority of them could not only demonstrate excellent functional results, but union by bony consolidation. Dr. Arthur Dean Bevan spoke of fracture of the neck of the humerus, and

reported three cases upon which he had operated. In these he had made the open operation, wired the fragments or had resected the head of the bone. He had one case of infection, which resulted in the loss of function of the shoulder-joint temporarily, and endangered the life of the patient for weeks. In the other two cases he obtained union by primary intention, and the results were satisfactory. Dr. A. J. Ochsner had followed the method of treatment described by Dr. Ruth, in a paper read before the American Medical Association, in sixteen cases, two of which died. There was union in all of them. The amount of shortening in all of them was less than three centimeters. He had made the open operation in one case only of ununited fracture with painful hip. He used two Parkhill screws through the neck and the head, but the result was not satisfactory, as it was necessary subsequently to remove the head. Dr. Alexander Hugh Ferguson had treated three cases of ununited fractures of the head of the femur by the open operation with very good results. Dr. Freeman, in closing, agreed with the speakers that in recent fractures of the neck of the femur the open operation should be avoided. He did not think there was as much danger attending the open operation from infection as Dr. Senn had intimated. Parkhill had used his clamp in fifteen or twenty cases without bad results. Infection, when it occurred, was along the tract of the screw into the cancellous tissue, and in his own case as soon as the screw was removed the infection subsided.

Cincinnati Academy of Medicine.

At a regular meeting held April 25 Dr. John H. Landis reported two cases of extensive carbuncle: Case I. Mrs. R., seen November 30, 1903, had a large indurated area on back of neck, which in ten days had spread from ear to ear and from occipital protuberance to seventh cervicle vertebra and showed hundreds of discharging sinuses. Albumin was found in urine during the first ten days. The temperature remained near 102° and the pulse at 100. Treatment consisted of sulphide of calcium internally with codeine for pain, and locally an ointment of icthyol, opium, and lanolin. The wound closed February 20, 1904. Case II. Mrs. O., seen January 23, 1903, was similar to above except that even a greater area was involved. After sloughing had ceased, the skin was found destroyed over an area as large as a large saucer. Treatment was the same as above, except that castor oil and turpentine were used locally.

Dr. R. C. Jones reported a case of chancre of the tonsil. Mr. S. had a sore throat; he had had a chill and general aching. On examination temperature was 102°, the left gave the appearance of acute follicular tonsillitis. After a few days swelling decreased but submaxillary glands became swollen and indurated. On pulling the tonsil forward a small but typical chancre was seen on the posterior surface. Later roseola appeared, followed by iritis.

Dr. Frank H. Lamb reported the following obstetrical cases. Case I was seen in April, 1902, while assisting Dr. James F. Heady of Glendale. L. S., thirty-two, mother of two children, the first having been delivered by podalic version and the second by high forceps. The pelvis was flat, with contracted brim and prominent sacrum; labor had commenced some time before and the os was dilated to the size of a silver dollar, the head was still above the pelvic brim. Under chloroform, high forceps were applied, and after forty minutes a dead child was delivered. The cause of death was that the cord, which was wrapped twice around the neck, was compressed between the forceps and the cranium. On December 5, 1903, Dr. Lamb delivered this patient of a living child with the high forceps. Case II. October 1, 1902, Mrs. B., a large german woman, mother of six children; labor had always been normal and easy. Examination showed the external os patulous and cervix long and cylindrical. The internal os admitted the finger tip. The vaginal fornix was boggy and the presenting part was indistinct. The woman refused chloroform, and digital dilatation was completed in one hour without. Chloroform was then given and fingers introduced into the uterus; they would not pass to the right, and to the left membranes were thick and tense cords could be felt; at this point several gushes of blood occurred. The membranes were quickly ruptured and delivery accomplished by podalic version. The placenta was discharged immediately after the child, and was found to be a battledore placenta with the cords inserted into the membranes at some little distance. The placental attachment was the lower right segment of the uterus, while the attachment of the cord was in the lower left segment, the veins from placenta to cord passing over the os. The hemorrhage had been caused by rupture of one of these veins. The child and mother both recovered. Case III. October 20, 1903, Mrs. W. P., twenty-three. Primipara, with a left femoral hernia, this was protruded and made tense by each labor pain and could not be reduced; it became very tender. Under chloroform delivery was accomplished with high forceps. After delivery the hernia was reduced without difficulty. Case IV. Mrs. W., six children, all labors easy. When six months pregnant she had a fall, striking her abdomen; she had pain and had to stay in bed for a day. Two weeks later she had an acute dysentery with bloody mucous stools and tenesmus. At seven and a half months the dysentery was repeated; two weeks later—March 13, 1904—she started to clean house, climbing on chairs, etc. That night she had irregular uterine pain, and the next morning at ten discharged liquor amnii and a small amount of blood. When seen at 2 P.M. she was waxy pale, restless, thirsty, and very weak; her pupils were dilated. The amount of blood found in the bed was not enough to account for the symptoms, and the placenta could not be found low down. The diagnosis of concealed hemorrhage was made. The patient refused chloroform, so digital dilatation was begun without. At 3 P.M. she had agonizing pain in the fundus uteri, contractions ceased and she began to vomit, the pulse became weak and irregular (130) and she became blind. Chloroform was given, os dilated, and an eight months' fœtus delivered with the high forceps. With the fœtus came clotted blood and large amount of black liquid blood. Pressure on fundus, to deliver placenta, expelled more clots, and with the placenta came others. The foot of the bed was raised, stimulants and ergot administered and heat applied. She reacted nicely; in an hour pulse 120, temperature 97.8°. The amaurosis continued for four days, when recovery took place. The placenta showed a patch as large as the palm of the hand, which had been detached.

Laryngocele.—Garel reported to the recent Congress of the Laryngological Society of France a case of this rare condition. He makes three varieties. In the first there is an external projection resembling goiter; in the second the projection is partly external and partly internal, while in the third it is entirely internal. Garel's case was of the third variety. His patient, a man of thirty-seven years, had complained for fifteen years of vocal disability. At first his voice rapidly became fatigued on slight exercise and finally extinguished. There was no respiratory difficulty. Examination revealed a polyp of the right cord, which, during phonation, placed itself between the ventricular bands. The right band and aryepiglottic ligament were inflamed and appeared as a bilobed projection from dilatation of the right ventricle. This was regarded as due to excessive air pressure below the polyp which dilated the little-resisting mucosa of the ventricle. After the removal of the polyp the laryngocele gradually disappeared. Garel has found recorded only four cases of internal laryngocele —*Archives Internationales de Laryngologie.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 3, 1904:

	Cases.	Deaths.
Measles	57	3
Diphtheria and croup	200	28
Scarlet fever	70	5
Smallpox	...	...
Varicella	...	...
Tuberculosis	334	162
Typhoid fever	118	13
Cerebrospinal meningitis	...	10

Infant Mortality in Norway—*Janus* contains an article by Dr. Alex Johannessen on infant mortality in Norway, in which it is shown that this country has the lowest of any civilized land, the proportion for the whole country being 95 per 1,000. In the towns it is higher (130) than in the country (86), and it is higher for boys (106) than for girls (89). As is the case everywhere, it is higher for illegitimate children (150) than for legitimate (93). It rises in the extreme north beyond the polar circle to 150. A peculiarity of the Norwegian infant mortality, and the chief cause of its low rate is the absence of the usual summer rise due to infantile diarrhœa. From investigation of the records of several parishes during the past two centuries, Dr. Johannessen finds a great improvement in the nineteenth as compared with the eighteenth century, the respective mortalities being 101 and 195. The bad record of the eighteenth century being mainly due to deaths during the month of January.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service during the week ended September 3, 1904.

MALIGNANT DISEASE OF THE LARYNX.*

BY D. BRYSON DELAVAN, M.D.,
NEW YORK.

THE object of this paper will be to indicate the progress recently made in the study and care of malignant disease of the larynx, to call attention to certain especial points of treatment which seem of sufficient value to demand investigation and discussion, and to offer some personal suggestions, general and special, bearing upon the subject.

The laws governing the nature and development of cancer in man are, of course, general, applying to the disease wherever located. This being true we are able to record an advance of great importance in the study of this affection.

Within the past two or three years a widespread movement has been made in the direction of the general scientific investigation of the causes and the specific nature of cancer. Funds have been appropriated and laboratories established for the purpose in this and several other countries. The work is in its infancy, and sufficient time has not yet elapsed to bring forth important practical results. Certainly it appears that the intelligent and earnest effort which is likely to be put forth in the investigation of the subject at the new centers of special research gives hope that much good may be accomplished. Already the English commission has established the fact that new growths of many of the typical kinds may be found in an almost infinite variety of the vertebrates, including quadrupeds, birds, and fishes. Its investigations have also seemed to place upon a positive scientific basis the time-honored proposition that, in the present state of our knowledge, *early radical operation offers the only reliable prospect of cure.* In the department of the physiology of the larynx, Crile of Cleveland, Ohio, has reported the results of his investigations as to the effect of certain irritations of the larynx upon the pneumogastric and the recurrent laryngeal nerves and upon various other organs, notably the heart, which the pneumogastric supplies. His observations are of vital importance in their relation to the surgery of the larynx, and mark an epoch in the progress of our knowledge of this subject, especially with reference to the proper management of patients under surgical care.

Lacking new suggestions of value as to the etiology and pathology of cancer, we may proceed to the consideration of the treatment. Before doing so, however, one point must be clearly understood. As long ago taught by Krishaber, carcinoma may originate outside of the cavity of the larynx or within it. Extrinsic laryngeal carcinoma is practically incurable by operation. Attempts at extirpation are dangerous and recurrence is almost certain. The best hope for temporary relief seems to be in the external application of the *x*-ray, and possibly in ligation of the carotids.

*Read before the American Laryngological Association at its twenty-sixth annual meeting, held in Atlantic City, June 2-4, 1904.

With intrinsic carcinoma the outlook is far more promising, and it is with the consideration of this form of the disease that this paper will exclusively deal.

The methods proposed for the treatment of laryngeal cancer which may properly be discussed are: (1) Internal medication; (2) Antitoxins; (3) Liquid air; (4) Ligation of the carotids; (5) The *x*-ray; (6) The ultraviolet and the high-frequency rays; (7) Radium; (8) Surgical methods: (*a*) endolaryngeal, (*b*) extralaryngeal.

Rapidly considering these in order as above:

1. There is no known drug, from arsenic to Chian turpentine, which will cure laryngeal carcinoma.

2. Its treatment by the antitoxins thus far proposed has been a failure, neither the serum of Coley nor that of Adamkiewicz having given any valuable results.

3. Liquid air, recently recommended in the treatment of superficial growths of various kinds, does not seem applicable in cancer of the larynx or even in external superficial epithelioma, and the method is not likely to prove of practical use in this department.

4. Ligation of both carotids by Dawbarn's method has never, to my knowledge, been followed by actual cure. In several cases, on the other hand, it has seemed distinctly to retard the progress of the growth and has resulted in such general improvement of the case as to have fully warranted its performance. In sarcoma its value is apparently beyond question. In inoperable cases, especially of the extrinsic variety, this method is well worthy of consideration.

5. The expectations which were aroused by the discovery of the *x*-ray have not been realized. With one exception not a single success by this means has been recorded. In the case reported from New Orleans the patient died of laryngeal cancer within a few months of the extensive advertising of its alleged cure. Dr. George F. Cott of Buffalo reports a case of partial extirpation of the larynx with recurrence in four months. Following sixteen exposures to the *x*-ray, the growth entirely disappeared, and at present, seventeen months later, the patient is apparently well.*

But while the *x*-ray is not proved actually curative, its value in alleviating some of the worst symptoms of advanced laryngeal cancer is becoming more and more evident. Pain is relieved by it and sometimes completely controlled. Excessive secretion and fetid conditions of the growth are done away with, and the progress of the disease has been, in many cases, materially checked. Sufficient testimony is now available to warrant the assertion that, on the whole, the *x*-ray has up to the present time proved the best means at our command for the relief of some of the chief symptoms of advanced carcinoma of the larynx. In the earlier periods of the disease the recognized necessity for prompt operative measures has made it impossible

**Journal of the American Medical Association*, December 5, 1902.

for the *x*-ray treatment to have received fair and extended trial.

6. The suggestion of the use of the ultraviolet and the high-frequency rays in the treatment of laryngeal cancer and the perfecting of instruments for their application to the interior of the organ are of so recent date that no results have been reported. With increasing skill and experience in the use of this method excellent possibilities are in store for it, and it is to be hoped that it will not be abandoned until it has been given an exhaustive trial. Ingenious instruments have been devised for its application.

7. The past year has marked the discovery of a new and very interesting agent, namely, radium, the therapeutic uses of which are of the same order as those of the Finsen and Röntgen rays.* Lupus and superficial epitheliomas have been cured by it, and a number of cases of inoperable carcinoma have been treated with it with considerable success. Exner treated a group of twenty cases in Gussenbauer's clinic with evident improvement in all; while some of the results obtained by Robert Abbe of New York have been remarkable.

Unfortunately, the radium rays, like the *x*-rays, are not without harmful effects. The rays which inhibit the growth of bacteria inflict considerable damage upon the surrounding tissues. The burns resemble those of the *x*-ray. No report of the successful application of radium to the larynx has been made.

The physiological difficulties in the way of the direct application of the radiants to the interior of the larynx and their liability to cause dangerous irritation to that organ have seemed sufficient practically to eliminate them in the treatment of intralaryngeal cancer. Already, however, an excellent applicator for the violet ray has been devised, and it is only a question of time when some happy inspiration may give us practical methods for the direct use of the others.

Thus far the various agents of radiant energy have not been successfully applied to the cure of deep-seated malignant growths.

It cannot be too emphatically stated nor too clearly understood, however, that most epitheliomas of the interior of the larynx are, in the early part of their history, absolutely and distinctly superficial epitheliomas. Now, the agents of radiant energy, without question, can cure and have cured superficial epithelioma; therefore, theoretically, they should cure early epithelioma of the larynx. Just whether they will or not remains to be practically demonstrated. By all means, therefore, let those who are enthusiastic in this direction continue in their meritorious and not unpromising course of inquiry. Success may be nearer than now appears.

Few cases of early epithelioma are operated upon before a week or two has elapsed after the arrival at a positive diagnosis. The application of the *x*-ray during this time could hardly do harm and might give results sufficiently good to warrant its continuance. This suggestion would be especially practical in cases in which operation is refused.

8. Reviewing the above, it appears that but a single resource, namely, the radiants, offers even the possibility of temporary help in laryngeal cancer, and we are reluctantly forced to accept the unwelcome proposition so long familiar to us, that, at the present moment, surgery is the only field which presents any certainty of success in the treatment of these cases. The specific for cancer has not yet been discovered, and until it is found the actual mechanical removal of the disease seems all that we can command.

The endolaryngeal removal of malignant growths has had some strong advocates, among them notably B. Fränkel of Berlin, whose statistics on this subject are interesting. Notwithstanding what has been written in favor of this procedure, the sentiment against it to-day is practically unanimous. Case after case of epithelioma has come to our notice in which attempts at removal of the growth have been surely and rapidly fatal. It may be fairly stated that endolaryngeal methods in this disease have been absolutely abandoned and the attention of the profession has been turned exclusively toward extralaryngeal means. As with many other new things, the beginnings of extralaryngeal surgery were not encouraging. During the first ten years of its history the average of life was undoubtedly shortened by it. In the last fifteen years, however, steady advance has been made toward a better understanding of the operative work, and a fairer appreciation has been gained of its possibilities and its limitations. This is proved by a comparison of the statistics of the past ten years with the older records.

Thus, before 1881, the mortality for forty-one total laryngectomies was 60 per cent.; that for ten partial laryngectomies was 40 per cent.; the average for both operations being 50 per cent.

Glück, who, up to the present time, seems to have had the most successful record, in 1900 reported thirty-four cases of total laryngectomy for malignant disease, with thirty-one recoveries from the operation, a mortality from operation of only 8½ per cent. Kocher, in twelve operations of various kinds for laryngeal cancer, had a mortality of 8.3 per cent.; those cured for over three years, 16.6 per cent.; those free from recurrence less than three years, 33.3 per cent.

The diminution in the death rate for the operation of laryngectomy from 1889 to 1900 was from 44 per cent. to 8.5 per cent. The increase in those remaining cured over three years has been from 7 per cent. to 15 or 16 per cent. during the same period of time; while the increase in those remaining free from recurrences for less than three years has increased from 13 or 14 per cent. to 33 per cent.

In thyrotomy, with removal of diseased soft parts, the permanent cures are as high as 44 per cent., while the death rate can be placed at about 11 per cent. Of the patients operated upon by Mr. Butlin 66.6 per cent. lived for more than three years after operation, while his death rate from operation was 9.5 per cent.

The expression "permanent cure" should be used in this connection with due consideration and fairness. Since recurrence may take place years after the removal of a growth, it is plain that no arbitrary limit of time can be fixed beyond which there will be an absolute certainty of permanent immunity from relapse. One-half, and in some instances two-thirds, of the patients reported alive and well at the end of the first year have died within three years. Three years is considered the minimum allowance of time in which to record a case as one of actual cure. Statistics based upon alleged cures of less than three years' duration are therefore worthless.

As has been ably suggested by Hartley, "The reason for the steady improvement in the results is to be found in the measures adopted to avoid the former frequent causes of death, namely, the aspiration pneumonia and the infection of the cellular planes inclosing the trachea and its extension to the mediastina." Of these measures, the avoidance of general anæsthesia, especially by means of ether, and the more frequent employment of cocaine may

*Abbe, *Washington Medical Annals*, 1904, Vol. II, p. 363.

be mentioned. Kocher has probably used the latter more extensively than anyone else for the purpose of preventing cough, controlling hemorrhage, and allaying pain. As has long been known, ether diminishes the reflex irritability of the trachea and bronchi and greatly increases the tracheal and bronchial secretions. Chloroform is better than ether in that it does not induce the same amount of secretion. In other respects it is open to the same objections as ether. Both, however, induce general anæsthesia, a distinct advantage with regard to pain and shock.

To a conscious patient the operation is far from agreeable, and even with all that cocaine can accomplish in the way of local anæsthesia, the pain of operation under it is very severe. On the other hand, under cocaine anæsthesia of the larynx, tracheal and bronchial irritability is not impaired, secretion is diminished instead of excited, and, as has been shown by Crile,* the tendency to a sudden reflex inhibition of the heart and respiration through irritation of the superior laryngeal branch of the pneumogastric nerve is avoided. Butlin also recommends the application of cocaine to the interior of the larynx to define more clearly the limits of the growth.

In addition to greater skill and discretion in the administration of the anæsthetics, it has been suggested that much good has been accomplished by the employment of the posture of Maas, later advocated by Trendelenburg and Rose, in which the head and shoulders of the patient are placed lower than the level of the body, to the extent that all fluids gravitate away from the larynx and trachea, and thus the necessity for a preliminary tracheotomy in many of the simpler operations and for the various tampon cannulæ has been done away with. With this proposition not all surgeons agree.

Glück's method, in complete laryngectomy, of dividing the trachea at the level of the upper rings and attaching its lumen forward to the skin, as successfully practised by Solis-Cohen in the case of Hickey, has given, according to Hartley, a better proportion of cures than any other device.

The closure of the pharynx from the wound and from the open end of the trachea has been attempted by several surgeons for the purpose of preventing infection of the peritracheal connective tissue in complete laryngectomy, and has given good results.

Such are the reasons advanced by leading surgeons for the improvement in the statistics of the past ten years. In the judgment of the writer, however, certain other factors as well as these have been at work, and it is his earnest desire that these factors should be recognized and appreciated.

1. Recent operators have learned from experience to exercise care in the selection of cases for operation.

2. Through the influence, mainly, of Mr. Henry T. Butlin, great advances have been made in the management of the less advanced cases. This authority has vigorously insisted upon the vital necessity for the early recognition of laryngeal cancer and for its immediate removal as soon as the small intralaryngeal growth, apparently malignant, has made its presence manifest. Mr. Butlin has, therefore, been the earnest advocate of thyrotomy in cases in which the soft parts have been to a limited extent attacked. In cases of more extensive involvement he performs partial extirpation. His aim, however, is to secure command of the patient before the progress of the disease has included important parts, and thus to rescue him from the peril of a complete laryngectomy. With masterly ingenuity and skill he has improved the details of his operative work and of the after care of the patient until his methods are unquestionably the best in use at the present time, as is proved by the successful statistics obtained by his followers and himself. Every point of his technique has been worked out with elaborate care and proved with exhaustive experience. His work entitles him to the highest credit, while his opinions as to the necessity for early radical interference, lately substantiated by the English Cancer Commission, are in harmony with common sense and with the convictions of all good surgeons with regard to cancer in other regions. In what he has done he has been ably seconded by Sir Felix Semon. The writings of these authorities form a brilliant addition to the literature of the subject of thyrotomy and represent the most advanced and reliable knowledge of the day.

3. In studying the statistics of the subject it is found that by far the best records have been made by such men as Butlin, Glück, Kocher, and von Bergmann. Every one of these is an accomplished surgeon who has had wide experience in this particular line of work, whose operations are performed in a hospital, and whose patients are cared for by assistants thoroughly accustomed to the handling of such cases.

Nearly ten years ago the writer urged before the laryngological section of the British Medical Association, the following proposition: "The time has long passed in which an unsuccessful attempt at laryngectomy by one not fitted for the work can bring anything but reproach to the operator and discredit to the operation. I am strongly of the opinion that, for a time at least, both the welfare of patients operated upon and the interests of science demand that the indiscriminate performance of capital operations upon the larynx should cease. In most great centers there are individual surgeons or groups of operators who are especially well-fitted, as to both personal qualifications and hospital facilities, for the successful performance of this work, as has been proved in many cases by the records which they have already made. Let such men surround themselves with the proper assistants, let them systematize their efforts, and use all diligence in the perfection of appliances and methods and in the study of the cases under them, and keep careful and accurate record of everything pertaining to the history of their work. Then resign to them the care of as many cases of laryngeal cancer as possible. When a sufficient amount of material has thus been collected, we shall learn whether the radical extirpation of laryngeal epithelioma is unjustifiable, or whether, as we have the best reasons for hoping, it is likely to establish for us a reliable means of cure."

The proposition was received with outspoken disfavor by many of those present, and it is rare that one meets a surgeon who will admit the justice of it. Ten years of extensive observation, however, have abundantly confirmed the views which it expresses, and its acceptance is urged to-day with more earnest emphasis than ever. Heretofore, the results of indiscriminate operation have been so bad that their records are unobtainable because suppressed. General confidence in the value of the operation has therefore been seriously impaired, which means that the statistics of the best operators are no criterion whatever of the results of the whole general mass of operative work. It may be set down as an axiom that an inferior operator *never* reports an unfavorable case. Among such operators failure

**Journal of the American Medical Association*, March, 1900.

is common and its sources can easily be traced to distinct violation of well-established rules. Many a patient has died from preventable accident whose life would have been spared if he had had the constant care of a highly skilled watcher. As has been eloquently insisted by Solis-Cohen, such a case should never be entrusted to the *interne* nor to the assistant without experience in such matters, but should have within reach an attendant only less competent than the surgeon himself, qualified to appreciate the special necessities of the patient, and to meet promptly any emergency that might arise. Mistakes hardly short of criminal have occurred in laryngeal operations done by inexperienced men working with absolutely no trained helpers. Small wonder that the reputation of laryngectomy makes slow progress under such possibilities of danger.

My proposition, fair in itself, has been strengthened by the experience of every succeeding year. It is wrong to tell the patient that his chances are 80 per cent. good, according to Butlin or Kocher, and then to operate upon him in such a way as to reduce those chances fourfold.

Special skill, special experience, and special equipment are sure to give the best results. Time and the necessity for keeping to the subject in hand forbid any discussion of the question of special hospitals. I have long believed, however, that in the care of laryngeal cases our present hospital system was defective in the arrangement of the medical staff, and that the highest perfection could only be obtained by the surgeon who had under him a resident surgeon-in-charge with a permanent specially trained assistant and nursing staff. Some of our foreign associates have already set the example in this direction. In it, or something approaching it, will be found one of the main secrets of their success. The brilliant scientific results obtained at the Mayo Sanatorium, in Rochester, Minn., furnish an apt illustration of the idea in mind. Nowhere, however, is it likely that it is so well exemplified as in the hospital of Kocher, the great Swiss surgeon, whose operations upon the neck, including over 1500 cases of goiter, have given him and his attendants unrivaled experience in the surgery of this region.

There are several other considerations which tend to the safety of the patient, and therefore to the success of operative work, especially in complete removal of the larynx. An important factor will be the personal characteristics of the patient himself. Account must be taken of his age, vitality, and general physical condition; of his temperament, his intelligence, and finally of his station and surroundings in life.

Age, absolute or relative, will shorten the natural expectation of life, and thus detract from the value of even a successful operation. It is less desirable to inflict such an ordeal as laryngectomy upon one whose days are already numbered than upon one to whom a fortunate operation may bring years of usefulness.

Again, upon the assured vitality of the patient will depend not only his immediate recovery, but the success with which he will ultimately rise above the physical depression incident to such a severe surgical measure. It would be instructive to know in how many of the cases of the disease in which death has occurred without recurrence within a few years after laryngectomy, the fatal issue had been largely due to the general effect of the operation.

Perfection of the physical condition in general and of certain organs in particular will add greatly to the prospect of success. Thus, on the contrary, certain impaired conditions of the heart or lungs will increase the liability to pneumonia, and other almost necessarily fatal complications; bronchial irritation of any kind, accompanied by cough and expectoration, will seriously affect the patient's comfort, and dangerously interfere with the successful progress of the cervical wound; gastric disturbance is an unfavorable condition, as will readily be believed by anyone who has seen the effect upon a recently operated case of a single attack of emesis, or of continued indigestion.

There are a number of cases on record in which the subject of a so-called successful laryngectomy has committed suicide; nor can we wonder that the ordeal of the operation and of the period of convalescence, the physical deformity incident to it, the impairment of the power of speech, the social ostracism of the higher order of man, and the physical incapacity of the lower, should call for rare equanimity and almost superhuman moral courage. The temperament of the patient therefore may easily become the determining factor in the success or failure of the result, while upon this, and upon his surroundings, and the intellectual ability to adapt himself in the most satisfactory manner to the latter, will depend the toleration with which he will meet his life. Unquestionably, laryngectomy should not be performed without a full understanding on the part of the patient and his friends of the nature of the operation and of its results. The ultimate results of partial laryngectomy are, of course, far happier than those of the complete operation, and the physical condition of the patient is infinitely better in every respect.

There are certain practical points to which I wish to call attention. Excessive secretion in the mouth and pharynx has often been a source of annoyance and even of grave danger during the first few days following laryngeal operation, and it may become important to use effective means for its control. While some surgeons doubt the value of drugs in this connection, the writer has several times during the past ten years seen excellent results follow the administration of belladonna. Under small physiological doses of this remedy the secretions will in some cases cease. The method is simple, little harm can come from it, and the end to be gained quite justifies the expedient.

Another matter which demands attention is the early diagnosis of malignant disease, and especially its differentiation from syphilis. The two conditions are constantly mistaken for each other. It must be remembered that laryngeal cancer may not only simulate tuberculosis or syphilis but that it may actually co-exist with either of them. Most frequently syphilis is mistaken for cancer. Time and again cases are sent for advice as to operation for the removal of a supposed cancer, when the administration of a course of the iodide of potassium would result in a speedy cure. So often does this occur and so easy is it to fall into this error, that the writer believes it imperatively necessary in every doubtful case to exclude the possibility of syphilis by a trial course of the iodide. When this simple measure has been neglected more than one easily curable case of syphilis has come to the knife. With regard to prognosis it seems impossible, in many cases, to judge from the appearance of the growth whether its progress is likely to be rapid or slow.

The question of the best means for supplying vocal power to the subject of a laryngectomy has been much discussed. The various forms of artificial larynx, so-called, have been failures. Their whistling tone is always of such quality as to render the wearer an object of remark, if not of derision. The

apparatus is uncomfortable and annoying to the patient, and its presence exercises an irritating effect upon the adjacent parts at a time when such irritation may easily excite a return of the original disease. Far better, when all semblance of the natural voice has been lost, are the results gained in Solis-Cohen's celebrated case (Hickey). The splendid work lately accomplished by Hartley of New York in this direction marks a genuine advance, and, as such, deserves to be recorded. As soon as possible, after the patient has recovered from the operation, he is placed under the instruction of an experienced teacher, through whom he acquires the art of communication by audible sounds, the latter generated entirely above the region of the larynx.

Questions relating to preliminary tracheotomy in operations upon the larynx have never been satisfactorily discussed. While certain of the best surgeons hold pronounced views upon the subject, it would seem that their opinions are sometimes more radical than the facts warrant.

1. Is preliminary tracheotomy a necessary measure in the treatment of laryngeal cancer?

2. If required, at what time with relation to the major operation should it be performed?

The necessity for a preliminary tracheotomy is now not universally conceded, many operators dispensing with it in certain cases. Murray* and Butlin maintain that it prevents the entrance of blood and septic matter into the trachea during the operation, and at the same time admits of the continuous and convenient administration of the anæsthetic, thus permitting a complete and satisfactory operation. In the more restricted operations, the employment of posture has largely done away with the necessity for tracheotomy.

More important than the above, because less understood and appreciated, is the vital question as to when, with relation to the major operation, the preliminary tracheotomy should be performed. Many surgeons, including Mr. Watson Cheyne, advocate the insertion of the cannula immediately prior to the main operation, on the ground that the patient is thus saved the anxiety and shock of two separate procedures, and because, as it is claimed, no special advantage is likely to be derived from its earlier application. It is also asserted that early tracheotomy subjects the patient to the danger of septic infection from the tracheal wound, and the tracheal wound itself to the danger of infection from the malignant growth.

In case of operations upon the tongue, jaws, or pharynx, this may possibly be true. In operations upon the larynx requiring tracheotomy, however, there is no doubt that many of the symptoms are essentially different from those present in the procedures mentioned above, and that for special and important reasons the plan of operating must be so conducted as best to meet them. The conditions referred to affect not alone the convenience of the operator and the mere comfort of the patient; they are based upon important physiological, pathological, and surgical facts. Upon the intelligent treatment of them will often depend the success of the case and even the life of the patient.

Of the physiological conditions which distinguish extensive operations upon the larynx from those performed higher up in the air passages the most important is the close proximity of the pneumogastric and the recurrent laryngeal nerves to the side of the wound. Just how much influence upon the successful progress of the case may be exerted by injury to these important trunks during operation or through irritation to them afterward from some of the various accidents of inflammation which may follow it is difficult to say. Doubtless, if the history of past cases of laryngectomy could be fully understood, much interesting and valuable information on these points would be developed. As a field for study, it is now an open one. There are many cases, however, in which the symptoms of phrenic irritation seem to have been distinct, and not a few others in which obscure symptoms would probably have found their explanation in it.

With regard to the actual insertion into the trachea of the cannula itself, it goes without saying that the irritation of this and other neighboring parts will be more severe immediately after operation, and that with the lapse of time the tolerance of the patient to the tube will be greatly increased.

More important even than the above are the changes which the wearing of a tracheal tube necessitates in the physiology of respiration. The sudden elimination from the process of breathing of almost the whole of the upper air tract with all which that implies, the exposure of the trachea and bronchi to air thus deprived of suitable preparation for its reception to the lungs, and, finally, the sudden increase in the amount of oxygen in cases in which preëxisting stenosis has been severe—all tend to disturb the general equilibrium of the patient and to cause, locally, a greater or lesser amount of annoying or even dangerous irritation.

It is highly desirable that at the time of the major operation the patient be relieved of as many as possible of these complicating factors.

Another consideration of interest in this connection is that, in performing an early tracheotomy, the changes of respiration are assumed at a time when the patient is in a quiescent state and when, being mentally and physically less disturbed than it is likely he could be after the major operation, he can with the least physiological irritation and the maximum convenience to himself, acquire a sufficient knowledge of the mechanism of the tube, the peculiar arrangement which it requires, and the effect of its use upon himself. The value of this preliminary experience has often been underestimated.

The performance of an early tracheotomy is thought by some to subject the patient to the danger of septic infection from the tracheal wound. While this might be possible when the cannula is inserted within a few days before the laryngectomy, it does not follow that it will take place if the tracheotomy be performed at a time sufficiently long before the former to allow the tracheal wound to be tolerably well healed. Septic infection or pneumonia, if either were to develop, could hardly be due to the influence of the tracheal wound if the latter had passed the stage in which infection is likely to occur.

Again, the general condition of the patient suffering from progressive laryngeal stenosis is invariably less favorable than when normal respiration is possible. The restoration of a sufficient supply of oxygen to the system is sure to be followed by improvement, especially in the anæmia, malnutrition, and depression which are generally present. In this respect, therefore, the preliminary operation is of great value as preparatory to the successful issue of the later one.

The effect of laryngeal stenosis upon the bronchial mucous membrane is, of course, irritating, and, especially in cases in which the dyspnœa has existed for some time, bronchitis is often present. This will be materially benefited by the free admission of air to the lungs and by the generally improved tone of the system which follows tracheotomy.

Finally, in all cases of inflammatory disease of

Annals of Surgery, May, 1897.

the larynx the severity of the symptoms is increased by the physiological use of the organ. The state of quietude which follows tracheotomy, from the consequent abolition of the respiratory movement of the larynx, is almost always accompanied by improvement in the local condition which may advance for several weeks. The advantages of this at the time of the main operation are obvious and, in cases in which the congestion has been such as to make it difficult to distinguish between diseased and healthy parts, are sufficient in themselves to warrant the loss of a few days' time.

Several of the surgical advantages of early tracheotomy have been generally recognized. Thus, much valuable time is saved at the performance of the later operation; the patient is saved a certain amount of shock, and possibly hemorrhage; and the undivided attention of the operator can be concentrated upon the difficult task which confronts him in the removal of the larynx.

Lastly, in that method of complete laryngectomy practised by J. Solis-Cohen and Glück, in which the severed end of the trachea is turned forward and fastened to the edges of the external incision in the neck, the adhesion which has already taken place after tracheotomy between the trachea and the wall of the neck becomes of greatest assistance in holding the trachea firmly in place.

When there has been no early preliminary tracheotomy and when, in consequence, the edges of the trachea must be stitched to the cervical wound, the free movement of the trachea in respiration makes it practically impossible to keep the parts properly together. In many such cases union has not taken place, the operation has been a failure, and the patient has died.

Early preliminary tracheotomy certainly possesses advantages which should claim for it our careful attention in spite of the number of those who hold it in disrepute. On the whole, in properly selected cases it is without doubt a valuable measure.

In conclusion, while the necessities in this matter are distressingly great and the progress of knowledge is very slow, every year brings some little advance. Improved technique, special skill, and the oft-repeated plea of Mr. Butlin for the early recognition of laryngeal cancer by the general practitioner and its prompt treatment by the specialist will steadily continue to improve results until the arrival of the day when there shall have been discovered for cancer a specific cure.

1 East Thirty-third Street.

Sarcoma of the Nasal Septum.—R. H. Johnston has collected records of seventy-one cases of this nature and analyzes them as follows: Round-cell tumors lead with 10. Fibrosarcoma and myxosarcomata follow with 8 each. Angiosarcoma is fourth with 7. Fifth on the list comes the spindle cell tumor with 4, followed by myeloid sarcoma, 3, melanosarcoma 2, angiomyxosarcoma 2, sarcomatous polyp 2, cavernous angiosarcoma 2, and melanoalveolar-sarcoma, endothelial angiosarcoma, myxosarcomatous polyp, osteosarcoma, adenosarcoma, and fascicular sarcoma 1 each. The unclassified tumors number 17. The youngest recorded patient in the list is 11 years—the oldest 70 years. In the second decade there are 4, from 20 to 30, the largest number in any decade 13, from 30 to 40, 9; from 40 to 50, 6, from 50 to 60, 3, and from 60 to 70, 7. The ages are not given in 27 cases. As regards sex, the females lead with 26 to 18 for the males. In 26 cases no sex is given. Thirty-one patients are recorded as having recovered after operation, while in 14 cases there was a recurrence in a short time or in the course of a few years. In the others the result is not given.—*The Laryngoscope.*

POST-TYPHOID PERICHONDRITIS OF THE LARYNX.*

By EMIL MAYER, M.D.,
NEW YORK.

SURGEON TO THE THROAT DEPARTMENT NEW YORK EYE AND EAR INFIRMARY; ADJUNCT ATTENDING LARYNGOLOGIST MOUNT SINAI HOSPITAL; FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION OF THE NEW YORK ACADEMY OF MEDICINE, AND OF THE AMERICAN MEDICAL ASSOCIATION.

At the twenty-fifth annual meeting of the American Laryngological Association, I presented the report of a case of this affection subsequent to typhoid fever, which was afterward published in the Medical Record of July 25, 1903, and in the Transactions of this Association for 1903.

The history, in brief, was as follows: Female, aged twenty-eight, typhoid fever in October, 1902. Discharged cured December 13, 1902. Slowly increasing dyspnœa, which became urgent, required tracheotomy January 13, 1903. March 11, 1903, gradual dilatation by Schrotter's tubes. April 20, intubated with the O'Dwyer tube under chloroform. The tube was worn for six weeks, when it was removed. Eight days later she was again intubated without chloroform, for increasing dyspnœa and, at the time of publication, was still wearing the intubation tube.

Her subsequent history is as follows: The intubation tube which I reintroduced June 8, remained *in situ*, the external wound promptly closed, food was readily swallowed, and except that the voice was but little above a loud whisper, there was no discomfort whatsoever. On July 1 she took a sea voyage and went to her home in Norway, not without some trepidation lest an unusual attack of seasickness might result in a sudden expulsion of her tube. She was prepared for such an emergency with proper instruments for reinserting the intubation tube, and also, should that be impossible of execution, she was possessed of a tracheotomy tube and cannula. Happily none of these precautionary measures became necessary and she returned to New York on the first of September, 1903, having worn the same tube continuously for three months.

On her arrival she reported that she was readily fatigued on slight exertion, and for the past six weeks had been much annoyed by a bad odor from the tube. During my absence from the city she prevailed upon my assistant, Dr. Yankauer, to remove the tube, which he did on September 1.

Twelve hours after removing the tube, dyspnœa began, which became more severe during the night and was quite marked in the morning. The whole larynx was red and swollen, the false cords could not be distinguished from the true, and the interior of the larynx looked like a red cone with a small opening at the bottom. It was impossible to reintroduce the large tube, and the largest of the metal tubes, children's size, was introduced.

September 3. While Dr. Yankauer was making preparations to examine her larynx she coughed up the tube, and she then breathed fairly well for two days, when I saw her. On examination I found the following conditions: The laryngeal interior was now distinguishable, though red and inflamed, without causing dyspnœa. A little mass of granulation-tissue appeared below the anterior junction of the cords. For the next five days she had no disturbance with her breathing and her voice became stronger each day. On September 10 she complained of some increase of the dyspnœa, and two days later the dyspnœa was marked on the slightest exertion. There appeared to be a fixation of one-half of the larynx on the left side, the right cord being perfectly

*Sequel to a case previously reported. Read before the American Laryngological Association at its twenty-sixth annual meeting held at Atlantic City, June 2-4, 1904.

distinct while the left was entirely hidden by a band running above the line of the false vocal cord, narrowing the lumen of the larynx. Below the cords, and about on a line with the cricoid cartilage, there were some thickening and narrowing of the lumen. A No. 5 Schrotter tube was now forcibly introduced under cocaine and was followed by expectoration of blood. The adult size O'Dwyer tube could not be introduced, but the largest of the children's size metal tubes was readily introduced.

September 15. Has been breathing comfortably through the tube. Directly over the head of the tube are two œdematous swellings which do not, however, encroach upon the orifice of the tube.

September 19. The tube was readily extubated under cocaine spray with no dyspnœa resulting. The œdematous swelling above mentioned has disappeared, and the general appearance of the larynx is more nearly normal in color than it has been at any previous examination.

September 22. Has had no trouble in respiration since extubation. Voice clear, but deep. Some thickening visible at the junction of the cords, both cords visible, the band on the left formerly hiding the cord having disappeared. Benzoin inhalations were ordered, but no local treatment.

May 25, 1904. It is now nine months since the last extubation, and at no time since then has there been any dyspnœa. The woman's voice is husky and deeper in tone than formerly, her general condition is that of perfect health; she has increased in weight, and attended to her usual duties, so that I believe that I may now state definitely that a cure has been effected, this being the first case recorded cured by intubation. It demonstrates one more success for the O'Dwyer method and a triumph for modern surgery.

The special points of interest are:

1. The unusual nature of its origin.
2. The length of time the tube was worn.
3. The ease of deglutition, after intubation.
4. The use of the child's size toward the last for a short time.
5. It is the first case of this affection cured by intubation.

25 East Seventy-seventh Street.

THE TREATMENT OF PULMONARY HEMORRHAGE.

By W. B. McLAUGHLIN, M.D.,
NEW YORK.

ASSISTANT RESIDENT PHYSICIAN RIVERSIDE HOSPITAL, NEW YORK CITY DEPARTMENT OF HEALTH (IN CHARGE OF THE TUBERCULOSIS WARDS.)

In reviewing the literature of pulmonary hemorrhage one is impressed by the prevailing belief that hemorrhage from the lungs is the same thing as hemorrhage from any other organ, that the same mechanical and physiological laws which determine its arrest in other parts of the body apply equally here. Some of the standard textbooks on medicine even go so far as to make such a statement. It is my belief that it would be extremely difficult to get a physiologist to agree to such a proposition. There can be no question but that the stoppage of hemorrhage in an elastic organ, which is constantly expanding and contracting, presents an entirely different mechanical problem from the same stoppage in an organ which is practically immovable. The obstinate and continued bleeding from a chapped lip or a slight incision over one of the knuckles, as compared with the behavior of an equal amount of injury on one of the more immovable parts of the body forcibly illustrates this point. In fact, when one considers the time element necessary for the coagulation of the blood in the lumen of a cut vessel, and remembers that the lung is undergoing a complete respiratory cycle from sixteen to twenty-five times a minute, it requires no additional evidence to convince one that in the arrest of a hemorrhage from the lung forces must be brought into play additional to those usually causing the spontaneous arrest of hemorrhage in other parts of the body. It is well known that in hemorrhage from the lung the air-cells surrounding the site of the hemorrhage become filled with blood, and it is frequently possible to percuss out areas of dulness in the neighborhood of the hemorrhage, due to this infiltration. Much has been written about the danger of this clot becoming septic, but, so far as I know, little stress has been laid upon the important part which it plays in the arrest of pulmonary hemorrhage; and yet it is this clot which, filling the air vessels while expanded, prevents their contraction and immobilizes that portion of the lung. In this manner conditions entirely unfavorable to the natural arrest of hemorrhage are converted into conditions entirely favorable, the bleeding point being immobilized and subjected to pressure, thus giving time for a clot to form in the lumen of the ruptured vessel.

Admitting the above premises, and remembering the infections to which this clot is liable, it follows that it is the duty of the physician

1. To adopt those measures which will assist in the formation of such a clot as promptly as possible.
2. To try and limit the clot to the smallest possible size which will accomplish the desired result.
3. To prevent the dislodgement of the clot, once formed, until sufficient time has elapsed for the eroded vessel to become permanently occluded.

To meet these indications one must decrease the reflex irritability of the lung tissue, and limit the respiratory excursions of the side from which the hemorrhage is coming. The reflex irritability may be controlled by many drugs, among which the bromides and chloral are in high repute. My own preference is for opium, as it is not only without a peer as a cough controller, but it lessens tissue metabolism, renders less oxygen necessary, and so reduces the amount of work which the lung has to do. In comparison with these advantages the theoretical disadvantage of raising the arterial tension is not to be considered.

To limit the respiratory excursions there is no measure more efficient than strapping the side of the chest from which the hemorrhage is coming. The adhesive straps should be applied with considerable pressure during forced expiration, and should cover the entire half of the chest from the axillary fold to the lower costal margin, the same rules which govern the application of straps in fracture of the rib governing here.

The advantages of this method are:

1. It favors the formation of a clot around the bleeding point, thus assisting in the prompt control of the hemorrhage.
2. It prevents the clot from becoming loosened or dislodged, thus preventing the recurrence of a hemorrhage once controlled.
3. The clot in lieu of being formed in lung tissue which is on the stretch is formed in lung tissue, which is relaxed; it follows, therefore, that there is less interference with the general nutrition of the lung, and less likelihood that the existing hemorrhagic infiltration will be followed by septic processes in the lung itself.
4. Upon removal of the straps the expansion of that side of the chest, and the consequent expansion of the air vessels of the contained lung, will loosen

up and favor the expulsion of any clots which may remain in the lung.

The question as to whether this method would increase or decrease the danger of inundating the bronchi with blood is one which only experience can decide. While it is undoubtedly true that opium, by decreasing the general reflex irritability would tend to allow the accumulation of blood, the same cannot be said of this procedure. The decreased movement, would, to a certain extent, favor its occurrence on the side from which the hemorrhage was coming, but this usually occurs anyway; *per contra*, the increased respiratory excursions of the unstrapped side would favor the expulsion of any blood which might enter the bronchi of that side.

My routine treatment has been as follows: Immediately upon the occurrence of the hemorrhage the patient is given a hypodermic injection of $\frac{1}{100}$ grain nitroglycerin and $\frac{1}{4}$ grain morphine. The adhesive straps are then applied to the side of the chest from which the hemorrhage is coming, and the patient is instructed to lie upon that side. Six hours after, if the hemorrhage has ceased, the patient is moved out to a summer house which we have (the building has no sides, and is practically out of doors). At the end of four days the straps are removed, and the patient is given a week of rest cure in the open.

While I believe it to be of great advantage to get a patient with hæmoptysis out of doors as soon as possible after a hemorrhage, the wisdom of such a course might be questioned were the sufferer not already acclimated to the out-door life.

My own experience in this method of treatment has been limited to seven cases. Four were of moderate severity, and two were severe; one was not severe as to the amount of blood lost in a given time, but the bleeding extended constantly over a period of more than seven weeks, during which time all the matter coughed up was blood stained.

In all cases the hemorrhage was promptly and permanently controlled, and in none of these was there any secondary rise of temperature. I do not believe that one could always expect such results as these, nor are the number of cases great enough to justify any positive conclusion. But I do believe that they have been sufficient in number and satisfactory enough in results to justify me in asking of the profession an extended trial of this method of treating pulmonary hemorrhage.

Hot Air Treatment of Diseases of the Genital Organs.—J. Salom presents the results of his experience in fifty-seven cases of genital disease treated by the application of hot air. The majority were cases of parametritis of a subacute or chronic character, and next to this, adnexal disease. The favorable results obtained warrant the author in claiming that the method is of especial value on account of its pain-relieving and resorbent properties. The apparatus described by the author is so adjusted as to include the patient's abdomen and the degree of heat applied varies from 100° to 135° C., according to the individual. In addition to the conditions already noted great success also attended the use of the method in cases of pelvic encapsulated exudates, in two of which the infiltration disappeared in from twenty-two to thirty applications. The induced hyperæmia was very efficient in closing up abdominal fistulæ following laparotomies. The method may also be used to advantage in combination with pelvic massage and other procedures in those cases in which a perimetritis is accompanied by a malposition of the uterus and adnexa, which results in a congestive hyperæmia.—*Wiener klinische Wochenschrift.*

NON-OPERATIVE TREATMENT OF TRACHOMA.*

By FRANK JUDSON PARKER, M.D.,
NEW YORK.
ASSISTANT SURGEON MANHATTAN EYE AND EAR HOSPITAL; ATTENDING OPHTHALMIC SURGEON TO THE PRESBYTERIAN HOSPITAL O.P.D.; CONSULTING OPHTHALMOLOGIST TO SETON HOSPITAL, SPUYTEN DUYVIL, N. Y.

THERE is probably no disease in the annals of ophthalmology about which so much has been written and of which there is so much to be learned, as trachoma. The effort to isolate the germ has successfully defied the most scientific investigators in the field of bacteriology. Yet the fact that it is a contagious disease has been firmly established. It is at present of great interest to the medical profession, on account of the crusade established by the New York Health Board to stamp out the disease among the children in public schools. The appointment of inspectors and the establishment of hospitals where these patients may be cared for is of far-reaching importance, and the results that have been obtained in the past two years of this régime are certainly most gratifying. And if this is kept up, the day is not far distant when this dreaded eye disease, which is responsible for so many cases of blindness that become dependents upon the State, will be seldom seen.

In order that my subject shall be properly presented to you, I ask your attention to a clinical picture of the disease trachoma:

There are two forms—the *acute*, characterized by violent inflammation—and the *chronic* or *non*-inflammatory form. The onset of these two varieties is quite different, but the ultimate result is the same. The inflammatory form, often spoken of as "Eastern" or "Egyptian" ophthalmia, begins with violent inflammation, profuse discharge, photophobia, and swelling of the lids. The duration of this stage varies with the virulence of the infection, the general condition of the patient, and the treatment.

After the acute stage has subsided, on everting the lids we find numerous soft elevations, or granulations as they are termed, over the entire surface of the upper and lower lids, and especially marked in the retrotarsal folds. These are the follicles that are most frequently overlooked in diagnosis, and especially in the treatment, and I believe they are by far of the greater importance.

The *non*-inflammatory form presents the same general appearance: The numerous follicles on the conjunctival surface of both lids, without the acute stage.

Why these two varieties should be so entirely different in their onset or first stage, and yet the second and third stages be the same, we do not know. In nearly all cases, the follicles cover the conjunctival surface of both lids; but I have seen cases in which only the lower lids were involved, and others in which the disease was well developed on the ocular conjunctiva. The form of trachoma that we see the most of in this country—and, in fact, every case that I have seen sent from the public schools—has been the non-inflammatory variety; and I consider this the greatest danger, because the condition may be well into the second stage without the patient being aware of any eye trouble. I have had many patients with well developed trachoma come to my clinic and say:

"I am here because the doctor sent me, but my eyes are all right."

The second stage of the two forms is the same. It is where there are no longer separate granulations, but a coalescence and general hypertrophy of the entire conjunctival surface of the lids, resulting from partial resorption of the follicles with deposit of cicatricial tissue.

These conditions lead to the so-called pannus or

*Read before the annual meeting of the Medical Society of the State of New York at Albany, 1904.

vascular keratitis and corneal opacities, which result in impaired vision, if not in blindness.

In the third stage extensive areas of scar tissue are formed in the conjunctiva which cause atrophy of the membrane, contraction of the lids, and incurving of the lashes.

Before I speak of treatment, I want to give you the microscopical picture of one of these follicles which I removed from the inner canthus of a boy ten years old: Size of the follicle, 2x3 m; attached to conjunctiva by a narrow pedicle, the entire surface covered with superimposed layers of columnæ and flattened layers of epithelium (conjunctival epithelium). The mass is composed of non-vascular accumulations of small, round cells. The neck and center of the growth is formed by fibrous, connective tissue, scantily supplied with small blood-vessels. The fibrous tissue breaks up into trabeculi, which enters the cell masses (lymphoid tissue), and subdivide into a fine reticulum.

The government immigration authorities, recognizing the contagious character of trachoma, have deported hundreds of immigrants on this account; and this restriction has already had its effect in reducing the number of cases in our large cities. It is not uncommon for the nurses and house physicians in our hospital to contract the disease. I have had personally under my care two cases in the higher walks of life, who took trachoma in the college settlements. The lymphoid infiltration of the conjunctiva is probably the result of germ activity. And what should the treatment aim to do?

1. To have a germicidal action on the infection.

2. To restore the hypertrophied membrane to its normal condition.

There are two ways of accomplishing this: the surgical, in which the follicles are broken up and expressed, and the medical or non-operative—to which I want specially to call your attention in this paper.

My position in regard to operation I can readily sum up in a few words—I believe that the cases for operation should be carefully selected, and that indiscriminate operation is productive of much harm. I consider it, not as a radical cure, but merely as a means to a cure and a shortening of the time of treatment. The treatment following operation is of the greatest importance; and these patients are very liable to consider themselves cured after they have left the hospital, following operation; and they are too often told that the operation will cure them. These operative cases, without the necessary subsequent treatment, are those in which relapses occur as bad or worse than the first attack.

There is one variety of trachoma in which I consider operation should not be performed; that is, where there are small, hard follicles either alone or with the soft variety. In these cases so much destruction of the conjunctiva is done in expressing them, that the membrane is sometimes left in the third stage or cicatricial condition. The operation in these cases merely hastens this stage. Through the courtesy of Dr. H. W. Wootton of the Trachoma Hospital, of the Health Board, I recently saw a case in which operation was done on a primary trachoma in the first stage. Cicatrices of the conjunctiva resulted and vascular keratitis over the entire corneal surface followed in two weeks and continued for a year. Dr. Wootton stated that he had seen five cases of pannus following operation on these cases in which extreme infiltration and hard follicles abounded. They cannot be removed by the operation, without extensive destruction to the conjunctiva. These cases of vascular keratitis following operation seem to me to be proof of the old theory of pannus being caused by roughened lids irritating the cornea, rather than the new theory that it is a trachoma *of* the cornea. I believe in the operation in all cases of well marked follicular trachoma of the soft variety as the best means of shortening the time of treatment; but as the great majority of these cases are among the lower classes, who are usually opposed to an operation—especially when anæsthesia is necessary—out of 600 cases treated at my clinic at the Presbyterian Hospital last year, about one in ten, when operation was advised, consented to submit to it; the others preferring treatment, no matter how painful or how long a time it required. At the New York Trachoma Hospital last year out of 18,000 cases 5,500 were operated upon. With this in view, and with the large number of cases to deal with, I determined to try the various treatments advocated and to ascertain the treatment that was most favorable in effecting a cure—and to the result of this, I ask your attention:

The general condition of the patient and the hygienic surroundings are of the utmost importance. As these cases occur almost entirely among a class of people who have little or no regard for the principles of asepsis, an effort should be made to arouse their interest in this regard and prevent the spread of the infection. For this purpose, I have printed directions, as follows, which are given to each of my clinical patients:

INSTRUCTIONS TO THOSE HAVING TRACHOMA.

Trachoma is a contagious disease of the eyelids, which if neglected will cause suffering and injury to the sight.

To avoid infecting others, those having the disease should observe carefully the following instructions:

1. They should have their own towels, handkerchiefs, wash cloths and toilet articles, and under no circumstances should they be used by others.

2. They should sleep alone.

3. Avoid rubbing or touching the eyes, as the contagion may be carried on the fingers and infect others through articles handled.

4. The hands should be cleaned often with soap and water.

5. Treatment should be attended to regularly and continued until pronounced cured by the physician.

I have found good results from this; and the fact of their having a contagious disease has been so impressed upon them, that the patients and their parents have sought further advice as to the details of the precautions they should take.

Proper feeding and out-of-door life are to be urged; adenoids and other hindrances to development should be removed. The one rule that I try to emphasize is, that the treatment should be continued until the patient is pronounced cured.

In the treatment of the eyelids, nearly all the astringents in the pharmacopœia have been tried. Silver nitrate, two-per-cent. solution, has met with favor among a large number. My opinion is, that it should never be used in a case of marked trachoma, on account of the silver stains which result from prolonged use. Formalin and citrate of copper have been recommended by some—but without further mention of the many treatments recommended, I want to give you the results of my own observations:

In the first and second stages of the soft follicular variety, I regard rubbing with a strong solution of bichloride of mercury (1-500) as a procedure to be highly commended, and the method of doing this is as follows:

A hard cotton applicator is rolled and dipped in

a 1–500 bichloride solution. After the eyes have been thoroughly cocainized, the lids are everted and the surface given a vigorous rubbing—especially in the folds of the upper lid, along the tarsal cartilage. This rubbing is done three times a week, and the patient is directed to use iced cloths at home, if the reaction is violent, which seldom happens, the treatment that the patient is directed to carry out at home is the use of drops of some organic silver solution, night and morning. This treatment is continued until the conjunctiva is smooth. It is followed by a solution of tannic acid, 40 gr. to the ounce of glycerin.

In the variety of trachoma in which the hard follicles are present, the one treatment that has stood the test of years, and still stands at the head, is the crystal of copper sulphate. A convenient form of using this is a crystal, ground smooth and mounted in a wooden handle. It should be applied to the conjunctiva with the upper lids everted, the patient looking down, so as to avoid contact with the corneal surface. The crystal is applied gently in the upper cul-de-sac and the same way in the lower. A solution is quickly formed by the tears. It is my custom to flush the eye with a boric-acid solution, removing the excess and relieving the severe pain which often follows this application. The frequency of the application is determined by the severity of the case. I have never used it over three times a week. The use of cocaine to modify the pain I regard as a fallacy. The momentary pain of the application may be lost, but the pain following the loss of the anæsthesia is just as bad as if no cocaine had been used. These cases are also given the silver solution for use night and morning.

In the third stage, with the cicatricial contraction of the lid and pannus, I have had good results from rubbing the surface with oleum ricini and making very superficial linear scarifications with the knife. The application of copper is indicated in many of these cases, and much benefit is derived from its use. The pannus is treated as a keratitis—with hot applications and atropine. The larger vessels may be divided at the corneal margin by the actual cautery. The use of the powdered jequirity bean, at one time in vogue, is little used at present. It is a rather dangerous procedure, and if ever used, it should be only in those cases in which there is dense keratitis and pannus.

To sum up in closing, *surgical* treatment should be advised only in those cases in which soft frog's-spawn granulations are present. It should always be followed by after-treatment. Operation should not be performed in cases in which the hard, deep-seated granulations are present, on account of the injury done to the conjunctiva in removing them. The habits and general condition of the patient are very important features to consider in preventing spread and effecting cure.

The *non-operative* treatment that I recommend is, the bichloride rubbing, with the use of one of the organic silver solutions night and morning. In the hard variety, the use of copper sulphate and the silver solution.

40 West Fiftieth Street.

Antivenene.—In a study of the venom of the banded krait (Bungarus fasciatus), Captain Lamb makes some observations on antivenene. He found that Calmette's serum, prepared mostly with cobra venom, had little or no neutralizing action for the krait venom, and the same result was obtained with the Australian tiger-snake anti-serum. It would appear, therefore, that for every venom its appropriate anti-serum will have to be prepared.—*Treatment*

MALARIA*

By R. CADWALLADER, M.D.,
San Francisco, Cal.

When requested by our president to prepare a paper for this society I cheerfully consented, thinking it would furnish a good excuse to myself for attending. I selected malaria, being a subject upon which I was then working, and of which I presumptuously thought myself well posted. I soon found that I had chosen too large a subject and persuaded Dr. Bates to take half of it. I have found it still too large, but, not having found anyone so accommodating as the doctor, I must perforce do the best I can. I find myself in the position of the German scholar who, after spending his life on the Greek ὁ μέν, ὁ δέ, on his deathbed bemoaned his wasted life; ὁ μέν was all, he said, one life could master.

Now I assume that you are all familiar with the parasitic amœba known as the plasmodium malariæ of the simple tertian. I shall call it a germ and will try to use English, not the polyglot of the microscopist. Give me credit for being able to do so if I wished, and I will credit you with understanding it if I did.

My article is based on over 300 cases of simple tertian, occurring this year in my own practice, of which I have kept notes and made blood examination in 251 cases. I refer to simple tertian always, for I have seen no other kind.

I will state the conclusions that I have come to. I want to state them, but not have you believe them unless borne out by your own experience. I don't want to hinder medical truth by any errors of mine. If what I state is true, it will win its own way; and I want you to understand that every statement is prefaced by "it seems to me."

Malaria is perhaps one of the most important diseases with which we have to deal. When we consider that many of earth's richest spots are uninhabitable, as the Mississippi delta and other low silt deposits, because of it; that it ranks above pneumonia, typhoid and other fevers and next to tuberculosis in its annual number of deaths in the Southern states, and that it is world wide in distribution, we can see that it is one of the greatest scourges of mankind. Our troops in the Philippines, our miners in Alaska, our workers in forests, our travelers abroad—nay, even our peaceful valley and orchard homes—are yearly suffering from some form of malaria. Probably not one of you fail to see many cases yearly. To handle it successfully makes or breaks a man in most of our valley towns. The climate of Northern California, with its warm, long summers, its cold but short winters, its exuberant vegetation, with increasing irrigation and a thickening population, not only causes its prevalence, but will favor its increase in future years. A sluggish irrigation ditch, with its cattle tracks and moss clogged sides, a low house surrounded by wind breaking trees, unscreened windows, and a large family of children, constitute a mosquito's heaven. And malaria is not an open enemy of mankind. It is not a frank, outspoken disease that we recognize and combat. It is sly, quiet, insidious. It cowardly steals upon one in the unguarded and unconscious hours of the night, not to strike down or kill outright, and so risk detection, but to inject into its victim's blood a subtle poison that shall lie dormant for many days and after other days of intermittent agony shall leave the exhausted, bloodless, and unstrung—child most likely—a prey for every passing epidemic or hereditary weakness it may have been born with. Could malaria's factor in our deaths

*Read at a meeting of the Northern District California Medical Society.

be graphically shown it would be appalling. But my time is too short for such familiar things, and I must hasten on.

At the close last summer I wrote a short article, published November 1 in the MEDICAL RECORD, in which I called attention to the fact that free drinking of water predisposed to malarial attacks. I reported 35 persons, living mostly on one street, 19 of whom had malaria, and to 8 of these 19 I had advised large quantities of water, and that these 8 had been my severest cases. Also, the observation that when the nights became cooler malaria increased rather than decreased. I suggested that hydræmia was a prerequisite to infection and cited the following facts:

That folklore was often based on truth, and the common caution about eating watermelons was more than a coincidence in time of ripening and was due to increased water consumption. That we were safe always in following Nature's indications in matters curative, and the drenching sweats and diarrhœas of malaria indicate lines of treatment.

That cooler weather, which prevented sweating while it also hindered the growth and activity of the mosquito, was still the time when malaria was at its worst, quoting Mannaburg that "in malarious regions the number of cases is usually materially greater during a summer attended with a heavy rainfall than during a dry summer. In tropical countries the first notable increase in the number of cases occurs when the dry season is first terminated by the autumn rains; but when the rainy season has continued a sufficient length of time to inundate, more or less completely, the surface of the ground, a decrease in the prevalence of the disease takes place. When, however, upon the termination of the wet season the sun regains its full vigor, the evaporation of the moisture from the ground that ensues causes the number of cases again to be largely augmented." (Mannaburg, in "Sajous Cyclopedia.") Or in other words, the cases of malaria exactly follow inversely the water excretion of the people, which may be taken as a fair index of the hydræmia of their blood.

That all the drugs of value from quinine to arsenic directly or indirectly favored water elimination and that purgation helped their action. I quoted Craig "of returned soldiers from the Philippines 65 per cent. showing estivoautumnal parasites in their blood, were suffering from acute or chronic dysentery." A vain effort to remove water from the body.

And I quoted Craig again, "that the administration of quinine in cases of estivoautumnal malaria, complicated by dysentery, not only removes the malarial infection, but, in many instances, the dysentery improves, and a return to health is more rapid." His explanation of this is that the intestinal membrane is invaded by the parasite, causing an irritation, and hence the diarrhœa; but it would seem equally plausible to consider it also as an effort to get rid of all the water possible. And not without significance, also, are his statements that "during the paroxysms the amount of urine passed is increased," and that in "tertian and quartan fevers convalescence is often marked by the occurrence of polyuria," and that "a slight polyuria is very common, and probably more so than is generally known," and also, that, on the whole, "there is little variation from normal in the specific gravity of the urine."

He also calls attention to how infrequently typhoid fever and malaria coexist, quoting Dr. Lyon's list of only twenty-nine authentic cases and giving but five as his own experience. He says, "As a rule, the malarial attacks occur during convalescence from typhoid fever," namely, after the characteristic diarrhœa of the disease is over.

It was to test the effect hydræmia had in malaria that I made the study of my cases this year, and the result of my study forms the *raison d'être* of this paper.

If all were equally susceptible, every bite of an infected mosquito would be followed by the disease. Allowing a large personal factor, we would start in the spring with one infected mosquito who poisons two men. A second crop is hatched, and from these two, four cases arise, and so on to the *n*th power and we have an arithmetical progression until cool weather kills the bulk of the mosquitos and the cases recover. But the reverse is true. We see a few cases early in the spring, usually in those sick in the fall. There are rallies and declines until autumn. During all the hot weather when mosquitos swarm and breed rapidly but few cases occur. When cold nights set in the mosquitos breed slowly and are sluggish coincident with a lowering of water elimination, when—*mirabile dictu*—behold half of our season's malaria.

I have arranged my cases with reference to this fact, including those only who were actually residents of Winters, and excluding all transient fruit-pickers. Being a fruit section, the population is greatly augumented during July and August. It would be unfair to include those whose history I could not follow. They occurred by months as follows: In January 0, February 2, March 3, April 4, May 7, June 15, July 14, August 30, September 25, October 58. I can also add what it is impossible to tabulate, that the severity of the attacks have been much worse since cool weather began.

It is plain, then, that some other factor enters into it beyond the bite. What common condition, I ask you, is present but a chill to the skin, a sinking in the water elimination, and a consequent hydræmia. I have grouped them by age, work, and habits, but this is the only constant condition I can find.

I want you to understand that I absolutely believe in the mosquito being the intermediary host. Manson himself never claimed the bite to be the only possible source of contracting malaria, though I will say it is the only practical way. I know too well how universal is the rule no mosquito no malaria. And I want to call attention now to what I shall more fully speak of later, that germs will exist in the blood a long time, weeks and months surely, before causing symptoms. This I know, and others have observed the same thing. If this be so, some secondary cause must interpose to help it or be opposed to prevent it. Since it invariably causes symptoms the moment the bodily health is lowered, I assume it to be the resistance of the cells themselves, which if lowered or lessened in numbers by fluid will allow the germs to increase.

Craig very properly calls attention to the antagonism between typhoid fever and malaria. He states that the combination of these diseases is very rare, and that he has only observed five instances in over 4,000 cases. "Of these five cases, four were combined infections of typhoid and estivoautumnal fevers, while one was a combined infection of typhoid and quartan fever. The latter is the only case in which the quartan parasite was demonstrated in the blood. The malarial attacks occur during convalescence from typhoid."

I ask you why this rarity and why of five cases in 4,000 only one was simple quartan and why none were the still milder tertian and why it always occurs during convalescence and not before. Malaria notoriously attacks those weakened and exhausted from any cause and why not a typhoid case just

before or during its first stage, and I draw the inference that something peculiar about this stage of the disease is the reason, and I suspect the diarrhœa that is so characteristic, and conclude that the blood is not hydræmic enough for the germ.

And this leads me to the next step that the profuse sweats of malaria and the very often present diarrhœa are efforts of Nature not only to eliminate toxins, but to thicken the blood. We know its results in this, and later I will show that a case of malaria that begins with diarrhœa will hold off for days before a chill ushers in the disease. Many summer diarrhœas of adults and infants that are treated as such are in reality malaria and will promptly get well under quinine.

As I showed last year, free drinking of water will favor malarial infection. The old belief of the danger of eating watermelons has its truth nicely hidden, and the converse is also true. Again and again I see harvest hands sleeping out, bitten by swarms of mosquitos nightly, escaping all symptoms until they stop work and sweating, and then in less than a week they will come to me with a history of a chill. Now, after treating a few families, you will notice that the children and young adults have it, but the grandparents, old and dried up, usually escape. If you find an old, little withered man or woman they are free. This may be from their lack of juices or from acquired immunity. In many cases of old residenters I am sure it is the latter, but even in newcomers the thin, dry grandparents escape. Malaria is practically a disease of childhood. So universal is it that few children escape, and their watery structure favors infection, until by years of suffering they win immunity.

Perhaps you have seen a man who has gone untreated for a long time and worn out the disease. He is weak, bloodless, and yellow, but he is as dry as if he had been baked. Every possible drop of water has been excreted and he gets well.

And here fits in another argument. Many cases only require purgation, to end in recovery. Once in a long while you will find a genuine case that has an idiosyncrasy against quinine. These are rare, but you find them, and when you do, hydragogue cathartics are better than any other line of treatment. And here is the next step, that quinine has the marked effect of increasing vasomoter constriction, as Sollman says, "a quickened pulse with rise of blood-pressure." This greater pressure increases the amount of urine excreted therefore, and lessens the water of the body. Now consider the substitutes for quinine. Except for arsenic, which relaxes the capillaries, but while doing this acts energetically on the intestinal canal, producing watery movements, they are all diuretics. In this list are methylene blue, strychnine, nitrate of potassium, iodide of potassium, myrrh, eucalyptus, lemon juice, guaiacal, and phenocol, pepper, etc.; every one of which have diuresis as their principal, if not only, action. While they are poor substitutes for quinine, the fact that diuresis is their only common action is a strong presumption that it is the line of their beneficial action. It is also well known that brisk purgation by mercury while taking quinine wonderfully assists in the cure.

I had one case of Bright's disease that bears on this subject. The lady was sick some weeks before I saw her with swelling of ankles and eyelids. Her headache, nervousness, and general condition were much worse every other day. I soon noticed it, and blood examination showed many germs, but I was so busy combating threatened coma and urine suppression that I let it go for a time. After packing, sweating, purging, and nitroglycerin I persuaded the kidneys to go to work and the headaches improved. The immediate need for malarial treatment ceased. Two weeks or so later another temporary suppression occurred, and the every-other-day trouble began until elimination was again effected. I then put her on treatment for malaria with no further trouble. What caused the malaria to show itself during times of non-elimination and to disappear during times of elimination of excess fluid? Mind you, she did not have a chill at any time that was noticeable, but the germs were there at all times.

In Hirt's "Obstetrics" are passages which, taken together, support this theory. In speaking of the alterations in the circulatory apparatus of the puerpera he says: "The whole volume of the latter (blood) is increased, but not by an equal increase of all the constituent parts; the corpuscles are relatively decreased in proportion to the liquor sanguinis; the watery element of the blood is proportionately increased, making the condition of the blood during pregnancy one of hydræmia. This is further marked just after delivery, but "at the end of two weeks it is much nearer a normal condition than it was in the latter half of pregnancy, although it is still somewhat deficient in red blood corpuscles and in hæmoglobin."

Under puerperal malaria I find "that the liability to infection is increasing after childbirth." The most striking phenomenon in the puerperal state is the reawakening of malarial manifestations, probably by reason of the traumatism and physical depression following childbirth. The third day after labor seems to be the usual time for the reappearance of the disease."

In speaking of puerperal sepsis, I quote again "the puerperal state excites almost surely a fresh outbreak of malaria that is latent in the system, even though it has been dormant for years. There is nothing to show that the woman is likely to contract the disease during the period of puerperal convalescence itself, but if she has never had it in her past life it is practically certain to break out before she rises from bed.

That malaria is likely to break out in this condition is a fact borne out by all experience, but I do not agree with the statement that it can remain dormant for years in the body. A malarial country has too many opportunities for infection, at least the season before, to be sure that infection is not comparatively recent. But this statement bears out the theory that an impoverished hydræmic blood is a certain prequisite to development of the germ.

Winters lies on the north bank of Putah creek; a torrent in the winter and a sluggish stream in the summer, with many pools of stagnant water, ideal places for mosquitos to breed in. There is a street parallel to it, the south lots running back to the bank. This street is undrained from one end to the other. Every family has malaria every year. The prevailing winds being from the south carries the insects into town. The farther from the stream in regular ratio the less malaria. The town has city water pumped from deep wells and remarkably pure. The mosquitos live all winter at room temperature. I had a few in my office all last winter. It is stated that before hibernation the female does not bite, and so is incapable of carrying over the germ. Of this I know nothing, but it is not needed, for the germ lives for months in the individual.

On numerous occasions during the past winter I found germs in the blood of those sick in the fall but now free from symptoms and supposedly well. I am quite sure of this, but I was not quite so expert then as I am now and might have been mistaken. But you can take any old-timer, one who has lived for some years in Winters, and you will find the germ

in his blood, and I want to impress it upon you that the germ can be found in those apparently healthy.

I have in mind one lady who has a chill every time she works hard, does her own washing or something of that sort. She will have one with its fever. The next day she is well and the day after another chill will come on. If neglected, a regular succession is established, but she knows enough to begin capsules with the first chill and so escapes with one only. This has not happened once, but many times. Another case is that of a gentleman born and raised here, who suffered with malaria as a boy, told me he and his brother could lie in the sun and let the wind blow on them and have a chill any time they wanted to for some years. He is immune personally, but his wife and three children have had several severe attacks this season. His blood shows germs present all the time. In these cases it seems dormant all the time, but I consider it the result of continual infection that, because of some condition of the body, will not allow the germ to increase to a numerical point sufficient to cause symptoms or perhaps to an acquired tolerance to the toxins of their life history.

As I stated before, it seems constantly present, for almost every disease is modified by it. To my surprise, this year a patient with whooping-cough hardly had any trouble except on alternate days, when twelve to fifteen paroxysms was the rule. The germ was there and quinine ended that feature. I mentioned a case of Bright's disease worse in every way alternately until free elimination of water took place.

It has been stated that dark-skinned races were immune. This is not true. The Japanese are the worst cases here. They live in a manner of greatest exposure and come to us with a history of never having had a chill. While hard at work and sweating freely they escape for a time, but as certainly as they lay off a few days they are sure to come down with it, and they have it hard, too. Daily or double infection is common. But, notice the bearing on the hydræmia, a hard-working, dried up, opium-smoking Chinaman rarely has any trouble. It is a matter of observation that they escape.

That there is a latency, is the consensus of opinion as I find it. That there is immunity from symptoms is more radical, but immunity is a relative term. There are persons, however, who have had malaria for years and at last are free even when surrounded by cases and freely exposed to mosquitos and bitten by them and with the germ in their blood.

These are immune in one sense, but occasionally, when run down in health, these very persons will become sick. It is from such that the fresh season's crop of mosquitos become infected, and any prophylactic methods will not succeed until they are treated as well as persons having symptoms.

Now an analysis of these 251 cases is not without deep interest as showing the types and forms met with and the percentage of each. Thirty of the 251 were repeated examinations in the same individual, which cuts us to 221. Of these, thirty-eight were examined prophylactically and thereby in the main escaped. I have left, then, 183 individuals in whom diagnosis was made or confirmed by the microscope:

Of regular every-other-day classical chills and fever	111	cases,	60.7 per cent.
Felt badly with perhaps some fever irregularly, but no chill	37	"	20.3 "
Pure neuralgias, regular or irregular	10	"	5.4 "
Infant diarrhœas conforming exactly to summer bowel trouble, no chill	6	"	3.2 "
Examination because leaving	2	"	1.0 "
Kidney case, worse every other day	1	case	0.5 "
Pertussis, worse every other day	1	"	0.5 "
Continued fever	2	cases	1.0 "
Ear worse every other day	1	case	0.5 "
Fever rising step by step as in typhoid, with no chill and diarrhœa	9	cases	4.9 "
Examined, germ found but not treated	3	"	1.6 "
	183	cases.	99.7 per cent.

Manson says that periodicity is the only sure sign of malaria. I want you to note that only in 62 per cent. of these cases was there any periodicity at all. His observation has not been mine.

Other thirty-eight were examined to see whether the germ could be found; twenty-four had it and in fourteen it was absent. These were taken at random, regardless of age, sex, or how long they had lived in Winters. They were apparently, and supposed themselves to be, free from malaria and were generally in perfect health. There were two cases that I classed as not having the germ that are doubtful. I think they did have it, but not being positive I classed them on the other side. Now let's see how they turned out: The fourteen free from germs have remained free up to date. Of the twenty-six with germs but apparently healthy, I put six on treatment at once. They remained well, but only twenty are now left.

Of these twenty, three were afterward examined and no germ found; too few for any result therefore, and all excluded; two began feeling so badly inside of a month that, knowing their trouble, I had to prescribe; one had a sudden hard chill nine days later; three found out that they had germs and confessed afterward to self-dosage; three began to feel malaria and left for the mountains. There remain eight in whom have been found the germ not once but more than once, and they remain healthy to-day. Now eight, at least, out of 251 have the germ without symptoms, all being examined prior to September 1, Of the eight two have moved away, leaving six available cases.

1. Mrs. S., native Californian, aged fifty-five, height 5 ft., weight 93 lbs., small, dark, dried-up little woman; germ first found June 23, lived in Winters over thirty years. Feels tired at times during summer for days, then better, never had a chill in her life.

2. Mr. L. H., single, native son, aged thirty-five, in Winters thirty years; has not had a chill for fifteen years surely; thin, spare, and dry. Chills in the same house three or four different times this year.

3. H. R., boy, aged nine; August 18, born in Winters; no chill for three years; very frail, thin, dried up; malaria in brothers and sisters.

4. E. R., sister, aged twenty-two, born in Winters August 18, no chill for three years; a year or two in the same house.

5. Mr. W., September 2, aged sixty-five, married in Winters fifty-five years; never had a chill since then; all his family have had them this year; thin, dry, withered.

6. J. W., born here, many chills as a boy, none twenty years; dark, dry, and thin; wife and children sick many times this year.

Now I realize that this is a remarkable statement and one not commonly admitted. As the old saying is seeing is believing, and you saw me prepare a few slides from Mr. W.'s blood. They were there a day or two ago and I guess we will find them again to-day.

Of these 251 cases 111 were instances of chills and fever not differing much from the well-known types. Five of these 111 cases were marked by purging and some fever, but no chill or intermittency. Six cases were in children, supposedly cases of summer diarhœa in nursing infants. One patient was sent to the mountains for relief and finally drifted to me after passing through several hands. The blood showed germs, and quinine ended the trouble in all in a few days. The improvement was from the start. My hydræmia theory furnished the hint.

Now regarding malarial diarrhœa or dysentery, I want to be honest and say that it is very hard to get at the cause of summer diarrhœa. Cold, unripe fruit, heat, etc., enter into it and make it difficult to state that any case has no other causation than malarial infection. But I have seen babies, showing a germ or two, suddenly taken with diarrhœa and with a little fever possibly. The case will act like one of diarrhœa of that age, the patient getting worse and worse until quinine is given, and in twenty-four hours the trouble is over, and at the close the germ can't be found either.

There is a close analogy between the skin and the intestinal mucous membrance, the ecto- and endoderm. We know the exhausting sweats of malaria, and it is not a wild guess to suspect the intestine to act in like manner. Both are active in eliminating toxins. I need only suggest this, and many facts of physiology and practice will flash into mind to confirm it. There is hydræmia of course, and an effort to get rid of the water.

Dr. William Britt Burnes of Memphis read a paper last May before the American Academy of Medicine on this subject, calling attention to this diarrhœa, and stating that the parasite and pigment were to be found in the vessels of the intestinal mucous membrane, and that these cases were promptly amenable to quinine therapy. I only confirm it, therefore; it is not original, but I try to explain it.

One was a kidney case and another whooping-cough, both previously mentioned, three ladies expected to leave and did not want to be sick away from home and were examined.

Twenty-seven cases began by general malaise and ascending fever as in typhoid. In some of these there was diarrhœa, in others constipation. There is no nicer test than between typhoid fever and one of these ascending malarias with diarrhœa. A slight sensation of chilliness may begin both. There is one symptom never seen in malaria by me, but very common in typhoid fever, *i.e.* a dicrotic pulse. Again and again it has saved me from doubt. My rule is to give a guarded diagnosis and to put in heavy malarial treatment for three days, if not better by that time typhoid fever is a certainty. I had nine of these typhoid type cases.

Now here is the history of one of these cases. Mr. B., aged twenty-five, from southern California, up buying fruit. For a week he was feeling badly. Tendency to constipation at first, then diarrhœa, no appetite and tired. Diarrhœa increases and he goes to bed July 30, and sends for me that afternoon. No chill at any time, but he had fever in the afternoon for a few days, bad diarrhœa, some vomiting, abdominal gurgling, tongue dry, brown, coated and tremulous, dull and apathetic, temperature 104. The next morning his temperature is 101½ and the next evening 103 and the morning of Sunday the 1st it was 102. No rose spots, too early for them anyhow. Now this looks like typhoid fever, but his blood was full of the germ Saturday morning and he began taking quinine 4 gr. every three hours that afternoon. As I said, Sunday the temperature was 102 in the morning, that night it was 102, Monday A.M. it was normal. Tuesday P.M. it went to 102 (note it is now showing an every-other-day tendency) and thereafter normal. A Widal reaction would be very nice, but we country practitioners can't keep serum on hand all the time. Three cases were neuralgia pure, but worse on alternate days, I found by questioning and observation. One lady wanted a tooth out that she considered the cause. In all three cases it was neuralgia of the fifth nerve.

I have never seen any eye diseases that could be attributed to malaria. They are admittedly rare and of doubtful etiology.

I notice, too, a class of old residenters with a chronic trouble of fatigue. No chill, no fever, nothing but exhaustion in hot weather. If there is a germ of laziness I believe it is a form of the plasmodium. They are wiry, no extra flesh, and they keep going by will power, and the result is the post-occipital pain of nerve exhaustion. From this class grow our neuralgias—at first on alternate days, but later in spells of a week or ten days at a time. They have become neurasthenic. God only knows how many are yearly driven to our insane asylums by the anæmia and a cachexia incident to malaria.

I had a group of patients, all of whom had malaria severely last year, and who had the germ in their blood this spring, come to me regularly every two weeks for examination. This is why my notes run to 183 on 251 cases. These are the thirty-eight prophylactic cases. Not one of these that came regularly was sick a day. Sometimes they would go a month without a dose, but if a germ was seen, treatment was begun and kept up four days. One or two became careless and suffered for it, but those who were regular escaped. So the microscope is a practical agent for prophylaxis in ordinary hands. I am far from an expert myself, and what I can do any of you can do as well or better.

In examination of the blood let me give you a few hints from my experience: Prick the ear after squeezing it, as it don't hurt much, and for the same reason the ear is better than the finger. Never tell a child you are going to prick, only scratch just a little. Take smear directly on to slide, not cover-slip. Don't stain, but examine at once with a $\frac{1}{6}$ objective and you will get good results. If in doubt use Wright's modification of Jenner's stain, mount in Canada balsam and examine with $\frac{1}{12}$ objective. This is a good rule to follow after using a $\frac{1}{6}$ direct without slip. Now if you find anything that looks like a germ in half the cells exclude it; it is too common. Never take any but isolated cells; if bunched there is too much crenation for accuracy. Exclude every doubtful-looking object. The germ is about one-fourth the diameter of a corpuscle, ringed in form; watch for this with its pigment on one side and the clear refractive center. See that it is in the cell, not on it. Crenation retraction of hæmoglobin and dust are the main causes of error.

And now a few words as to how I treat a case of malaria: I give an adult four grains of quinine in a capsule every three hours with about the same number of grains of bromide of sodium in water to follow. I like the effect of capsicum with the quinine. My stock prescription is

℞ Quininæ sulph. ..... ℥j
Pulv. capsici ..... gr. xv
M. et div. in capsules No. xv.
Sig. One every three hours;

and

℞ Sodiæ bromidi ..... ℥jss
Aquæ ..... ℥iij
M. Sig. ℥j with each capsule.

This sodium-bromide solution removes nearly all the unpleasant head and ear symptoms. With this you must obtain free catharsis. One or two grains each of calomel and compound extract of coalocynth in capsules every two hours until free catharsis results is my rule. For the fever I give one of the synthetic antipyretics.

For children, or when a capsule cannot be given, I have had results from tasteless quinine. Methylene blue, arsenic, etc., are absolute failures in my hands and do not even modify the disease.

Dr. W. E. Bates of Davisville once asked me if I

had ever seen a case that quinine would not cure. I never have, and suspect in such a case that it has not been absorbed. Quinine unaided by catharisis is in large measure wasted. I have never failed, if I saw the patient during the fever and could begin treatment in the interval to stop the next chill. I care not how long it has been running. But as I stated, my experience is with simple tertian fever.

Dr. King has suggested that quinine acts because of its fluorescent property in the blood. I don't believe it at all, but it is an ingenious idea.

What I have called my hydræmia theory then is this: That a prerequisite to infection, or at least to symptoms, of malaria is a watery condition of the blood, and just in proportion to the total fluid in the body will be the severity of the disease.

These, then, are the few facts, analogies, and arguments in favor of the hydræmic theory. I believe it fully myself, and shall until I see stronger reasons against it. I call it a good working hypothesis and admit that it is not proven. I ask you all to accept it as a theory only and to seek to prove or disprove it.

PRACTICAL HYGIENE IN THE PUBLIC SCHOOLS.*

By ROSWELL S. WILCOX, M.D.,
PROVIDENCE, R. I.

In matters educational the signs of the time are most hopeful. To those of a strictly practical turn of mind, unable to appreciate results except in dollars and cents; to the pessimist in general, and to all others unable to read between the lines, these signs of hope may not be apparent. But to the careful student of pedagogy, a retrospect of the year's educational progress throughout the United States reveals changes vast and far-reaching, ones ultimately destined to advance all branches of human activity. For the public school system, in large part, lays the foundation upon which the interests of our country are to stand or fall.

President William DeWitt Hyde of Bowdoin College, in an address before the National Educational Association at its recent session in Boston, gives us a panoramic view of what our educational system would be were it everywhere as good as the best that anywhere has been attained. We should have small boards of education composed of the best citizens; having attractive buildings we should utilize them both summer and winter, day time and evening, for both children and adults, in the service whenever needed of social as well as of intellectual ends. But what is to me of more interest than any of the foregoing, provision would be made for special schools for abnormal children, rigid medical inspection would be instituted, district nurses would be at our service and public sanitation and school hygiene would be elevated to their proper position in the school curriculum. While the elements of such an educational system are all present at isolated points, the general standard is still low. Granted that an institution, an organization or a system is no stronger than its weakest point, then we must admit the weakness of our school structure.

Inadequate attention to the preservation of health and the prevention of disease in public school life constitutes a weakness for which we as citizens are in many cases plainly responsible. I use the word "inadequate" advisedly, for that due consideration along certain lines is being paid to the health of our school children, none will deny. Such zealous attention in the past, however, I believe to have been largely spent in improving the character of school appliances and the sanitary conditions of school buildings. But I cannot admit that liberal and increasing attention to physical and personal hygiene has as yet become at all general. Only in a few of our larger cities, with Boston, Chicago, and New York forming the vanguard, do we have rigid medical inspection, district nurses when required, and sanitation and hygiene receiving a more intelligent consideration as studies worthy of our attention. "As a general thing, school authorities very imperfectly realize how important hygiene is for school life. They are content to allow teachers to remain in ignorance of this knowledge, or to accept as evidence of sufficient experience, certificates which guarantee merely a superficial and second-hand acquaintance with this all-important subject."

First of all, then, it seems to me that the public should be brought to a realization of the need of a right physical start in education. The demand will then come for teachers better versed in physiology and hygiene, and for a revision of many of the present-day school books on these subjects, in strict accordance with the teachings of preventive medicine.

The author very distinctly remembers physiology and hygiene as taught in the public schools of Providence in the late eighties. Teaching was from textbook alone, and that from a "temperance" physiology. In a book of 374 pages, 72 were devoted to narcotics and 41 to personal hygiene. Temperance seemed to be the chief topic, and physiology and hygiene were prostituted to a furtherance of the cause.

Teaching was always by the "terrible example;" the trembling hand, thick speech, dull senses, poisoned blood, confused brain, foul mouth, and offensive breath were too conspicuously held up to view. How many of us in later years have come to believe that "the majority of beer drinkers die from dropsy;" that alcohol is a virulent poison and should be classed with arsenic and mercury, or that "tobacco has done more to cause insanity than spirituous liquors?" Extreme care was taken that all matter pertaining to alcohol should not be placed in a separate chapter. Rather, "facts" about alcohol and the bones had to be studied in connection with the bones. And so on through the various chapters, alcohol and tobacco were liberally sprinkled in.

Undoubtedly untold good has been done in strengthening the morals of many young men and women through the dissemination of such temperance knowledge. But why emphasize this broken law of health at the expense of so many other equally important laws of hygiene. Why make physiology entirely subservient to one branch of hygiene, the ill effects of the excessive use of alcohol upon the human system?

The tendency of the present day in law, in medicine, and in the various arts and sciences, is toward specialism. In the domain of medicine preventive measures even now appear conspicuously above the horizon and are destined to be *the* specialty in the near future.

The oft-repeated truth, "An ounce of prevention is worth a pound of cure," gains added force and much significance in its application to the physical welfare of public school children.

Physical training has its staunch supporters; others there are who have argued and labored and fought for the best attainable school buildings, fixtures, and appliances, all in accord with the laws of hygiene and sanitation. All such work is indeed laudable, and should meet with hearty approval and coöperation. But still another class of public benefactors are studying the child himself, believing that

*Read before the Research Club, Providence, R. I.

"most delinquencies of backward children are due to physical defects, and that it is a paramount duty of municipal authorities and health boards to see that children in schools are not suffering from any complaint which might blight their own lives or spread among their fellows" (MEDICAL RECORD, June 13, 1903).

Locke says, "Nothing can enter the mind except through the senses." Such being the case then, we could hardly expect an individual with defective senses to gain other than defective knowledge of the world about him. Great injustice is often done children by accusing them of obstinacy when they are the subjects of physical defects of the eyes, the ears, or the throat. Time was when children were cudgeled if they made mistakes in spelling, while at the present day children are sometimes whipped or otherwise punished for so-called "careless" writing. Repeated and careful investigation of children's eyes have conclusively proven that in a large percentage of cases, at least, these apparent instances of carelessness and stupidity are due to defects of vision.

Risley of Philadelphia, Smedley of Chicago, Agnew of New York, and Allport of Minneapolis have shown that, "taken as a whole, fully one-third of the children in the schools have eye defects that interfere with the best development of mind, and body as well." As Dr. Risley says: "Many a boy who gets on indifferently at school, gaining a reputation for dulness or indolence, is prevented from going forward by his imperfect vision—a condition of which he himself may be ignorant. How is the child to know but that the blurring page, the watery eyes, the aching head which follow any protracted use of the eyes, are not the common lot of mankind? This has always been his experience; why should it not be his fellows, also? The humiliation and loss of self-respect in these cases robs life of much that gives it value, 'and the discovery and removal of the cause of such loss is a matter of no small importance.' 'And such cases multiply themselves over and over again to one who is looking for them.'"

To quote Superintendent Whitcomb of the Lowell (Mass.) schools: "The worst feature of the case is that the schools are mainly responsible for the impaired sight of their pupils. The work in reading, writing, and drawing imposes the severest possible strain, and results everywhere show that the eyes yield to the pressure in constantly increasing numbers as the years of school life go by. Few children are near-sighted when they enter school; the savage never becomes so; myopia is the concomitant of civilization, and schools are what Dr. Scripture of Yale calls them, 'bad eye factories.'"

Probably among the most prevalent of these defects and diseases of the eye, astigmatism, myopia, and trachoma take the lead. In astigmatism the muscular and nervous strain is so great as to produce exhaustion toward the end of every day and to result in a ceaseless drain upon the nervous system. In myopia or "near-sight" objects are never seen clear cut. Of eye diseases, strictly so called, trachoma or contagious granular lids is undoubtedly the most common of all affections during school life. Such was found to be its prevalence upon preliminary investigation among the school children of New York, that it eventually led to the adoption of rigid and systematic medical inspection for all eye defects; where once the chief attention of the teacher and physician was directed to the diagnosis and exclusion of the common infectious diseases, thereafter special attention was paid to physical defects in general.

If unrecognized and untreated, these eye affections lead to dire results, but when detected and properly treated, a cure or alleviation of symptoms may be expected in most cases; careful and sympathetic attention to such work on the part of the school authorities is, I believe, of as true and as fruitful philanthropy as can anywhere be found.

Quite as serious if less numerous are those children "who having ears, hear not." Deafness, however, cannot be considered a "school disease" in the same sense in which many diseases of the eye are such. Examinations conducted among thousands of school children in New York, Chicago, Glasgow, Copenhagen, and elsewhere have shown that some 18 per cent. of such pupils have auditory defects of various kinds and degrees, and that, laboring under such a handicap, they cannot be expected to profit fully by the work offered. Examples are not hard to find in which a boy or girl, supposed to be lacking in that which we call "brains," has made rapid strides in school after the teacher has made sure that everything said was understood.

Still another class with physical shortcomings are those children found to be suffering with throat difficulties, due in many instances to adenoid growths, the so-called third tonsil. Such growths, obstructing the respiratory passages, prevent natural and healthy breathing, affect the hearing, sap the system of its vitality, and tend to induce a condition of listlessness and so-called stupidity. Probably 10 per cent. is a low estimate for those found to be "mouth-breathers," with adenoid growths as *the* contributing cause. Dr. Durgin of the Boston Board of Health says that 169 cases of such growths, all perfectly curable, were discovered in Boston schools in the first year of medical inspection there.

The foregoing physical defects do not embrace all of the adverse conditions under which public school children labor. No indeed! they are simply those which are startlingly common. Others there are even more intimately connected with the nervous system.

Kollman says, "Thirty per cent. of the school children of Europe have abnormal nervous systems, and this nervousness is a prolific source of crime." I trust this casual survey of the physical side of school life may serve as a basis for my text, "Practical Hygiene in the Public Schools."

Since the effects of adverse conditions must be recognized before they can be prevented or treated, it seems to me essential that all schools should have systematic expert medical inspection. Otherwise the combined efforts of the various educational agencies must meet with a measure of defeat. It would ill become me at this time and place to discredit the efforts put forth along this line by some of the more thoughtful, progressive, and sympathetic teachers. But I believe their labor has been largely spent in the recognition of infectious diseases, such as measles, scarlet fever, and diphtheria, and in the detection of repulsive and contagious skin diseases, as, for example, ringworm, pediculi capitis, scabies, etc. Many times these diseases gain considerable headway and scatter the germs of contagion far and wide before they are properly diagnosed. And so it seems to me that there is an apparent need of competent medical advisers to assist the teachers in the detection of the first stages of such diseases. After such a system of medical inspection has once become thoroughly organized, instruction by means of lectures, pamphlets, and clinical demonstrations would enable the teachers themselves to diagnose properly some of the more prevalent of these complaints. And yet, personally, I believe that most teachers find enough to occupy their time fully without devoting a portion to a search for sick children. Let the medical inspector (in those places fortunate enough to possess such an official) seek out the lame

the blind, and the halt at stated intervals and keep a record from year to year of the growth and development of such pupils. These diseased and defective ones could best be detected, treated, and counseled by a physician. Every moment of time which the school program and teacher's strength would allow, could then be more fittingly devoted to instruction in those branches of hygiene which pertain to home as well as school life.

This is the time to do some noble work along the lines of preventive medicine. Such instruction would very materially aid in stamping out epidemics, and vital statistics would probably show a great falling off in such dreaded diseases as syphilis and tuberculosis. One of our members has said, "medical inspection can do its best work in the primary and grammar grades, while physical training should be prominent in the high school." The same authority, moreover, claims that one absolutely necessary condition in school inspection is harmonious and combined action of the school board, Board of Health, and the physicians. All are necessary, and if one is antagonistic, medical inspection will fail. I would heartily endorse these statements of Dr. John H. Bennett before the New England Association of the School Superintendents in Boston, November 10, 1899.

Awaiting the coming of medical inspection into our public school system, some of the more progressive superintendents, principals and teachers, interested in all that pertains to the health of their pupils, have addressed circulars to the parents, giving a few suggestions relating to the habits and health of the children. This method was instituted in all the schools of Brooklyn during the régime of Dr. William H. Maxwell as superintendent. It is perhaps no exaggeration on my part to say that such circulars contained more practical up-to-date information on personal hygiene as applied to school children than is found between the covers of most of our present-day "temperance" physiologies.

A few quotations from one of these most excellent circulars might be appropriate right here: "To parents: 1. The health of your children is paramount to every other consideration. When children particularly girls, between the ages of ten and seventeen, exhibit evidences of nervous disorder, such as twitching of the face and hands, or extreme irritability, it is a sure sign either that the school work is too severe, or that they are not living under proper hygienic conditions, or both. In all such cases school work should be either materially lessened or intermitted until there is a restoration to health.

"2. When children study or read either by sunlight or by artificial light, care should be taken that the light is sufficient, and that it falls upon the page from the left.

"3. The following practices should be prohibited, as being injurious to health: Study before partaking of food in the morning; the rapid reading of lessons just before the beginning of a school session; study during the noon intermission; study immediately after the close of school, before mind and body have been rested by play or other suitable change of occupation; study immediately after eating a hearty meal."

Other principals and teachers realizing that health is paramount to every other consideration, assume that all the circumstances relating to the well-being of the pupils, should be known to the school officials, in order that no adverse conditions may be allowed to exist. To this end a set of questions, "information circulars," as they are called, are addressed and sent to the parents of each pupil with a request that they be signed and returned. Amesbury (Mass.) High School pursues this method with most gratifying results. All information is gratefully received and confidentially considered.

Briefly, these questions may be said to embrace the physical condition of the child, his recreation, sleep, and personal habits, and the relation of school work and home duties. In reply to my queries the principal, Forrest Brown, A.M., kindly wrote: "(1) Circulars are given to pupils at the end of the first eight weeks or at mid-term. (2) One hundred and fifty-seven out of one hundred and fifty-eight complied with the request; no return postage. (3) Information for the most part was thoroughly reliable and assisted us greatly in directing the work of the individual pupil; in fact, it is almost impossible to estimate the value of the data furnished us in answer to these questions."

And briefly, now, as to what a few other cities are doing along similar lines.

Cambridge, Mass., established a system of medical inspection of children in the schools February 26, 1896. Its original purpose was to further the crusade against contagious diseases, but as the system has developed, careful scrutiny has been maintained over all physical shortcomings of the children.

Hartford, Conn., also has a comparatively complete system of medical inspection. It is a branch of work which has constantly grown in importance and is under the direct supervision of the Board of Health. Since its inception during the diphtheria epidemic of 1899, it has come to be demanded by the public as a necessary protection for their children against all kinds of contagious affections to which they are liable to be exposed while at school. To quote the President of the Rhode Island State Institute: "It is not to be supposed that perfect attendance or perfect health is guaranteed by medical inspection, yet it is reasonable to expect that it will prevent much needless suffering and sickness, and tend to increase the efficiency of the schools by permitting a better attendance."

Providence, R. I., has done some excellent work since 1896 along closely allied lines dealing especially with backward children, and I may add with most gratifying results. Medical inspection, strictly speaking, while favored for years by the Superintendent of the Board of Health and others sufficiently well-informed to enable them to speak with authority, has not until quite recently entered into the program of our public school work, but once inaugurated we feel confident that the work will speak for itself.

In recapitulation allow me to state that:

1. "People must be made to understand that it is no disgrace if their children are not so strong, nor so receptive as their neighbor's. It will be an immense gain when the parents shall be made to understand that mental vigor depends largely upon bodily health" (MEDICAL RECORD, September 6, 1902).

2. "Only the knowledge gained not at the expense of health, but accompanied by health, can be of real service. Education must mean better health if it is to mean anything."—*Rhode Island Science Monthly.*

3. Practical hygiene in the public schools, successfully carried out, is evidence of a growing recognition that home and school are parts of a single life; that the school is made for the health, happiness, and usefulness of the children; and that the breakdown in health of a schoolboy or schoolgirl from preventable causes is murder of the first degree, for which high averages cannot atone.

In conclusion, allow me to quote from the *Providence Medical Journal* that "repetition is the basis of all education, and repetition of the truths ad-

vanced by our health boards will in time educate our educators.

The Influenza Bacillus as the Cause of Cholecystitis.—J. Heyrovsky considers that it has already been proven that the influenza bacillus, aside from its toxic action on the general nervous system, may also bring on an inflammatory process in any organ of the body. A hitherto undescribed localization of the bacillus in a gall-bladder filled with calculi is reported by the author in a patient who had cholelithiasis with irregular attacks of colic, closure of the common duct, and subsequently signs of a biliary infection for which operation was undertaken. The patient had a slight bronchitis which developed into pneumonia after operation, but from which he recovered. Several months later a fistula was still present, which discharged pus freely. Examination of the pus from the gall-bladder at the time of operation, and also that discharging from the fistula, revealed the presence of the influenza bacillus, and the latter was also demonstrated in the sputum during the pneumonia. The author thinks that the path of infection in his case was through the intestinal canal, the patient probably having swallowed some of his own infected sputum. The gall-bladder was rendered more susceptible to the invasion by the fact that it was the seat of a cholelithiasis.—*Wiener klinische Wochenschrift.*

Diphtheria in the Tropics.—Aldo Castellani declares that it is generally admitted by the writers of tropical medicine that diphtheria is infrequent in subtropical countries and extremely rare or absent in the tropics, and that when it occurs there it mostly exhibits a mild character. He gives the history, however, of a girl aged seven, daughter of a European planter who had never been out of Ceylon. She presented all the clinical symptoms of diphtheria and died in two days. The bacteriological examination showed the presence of a virulent Klebs-Löffler bacillus, which killed a guinea-pig in two hours. It is certain that this was an indigenous case of true diphtheria. This case, together with the previous observations of Perry, Fernando, and da Silva in Ceylon, and Plehn, Cornwall, and others in other parts of the tropics, tend to demonstrate that diphtheria is not limited simply to the temperate and subtropical zones, but is a true cosmopolitan disease. It occurs, probably, far more often than hitherto supposed, in tropical countries. The different climatic conditions, perhaps, influence sometimes the characteristic clinical features and course of the disease, and this fact, if a bacteriological examination is not made, may make the diagnosis difficult and cause some cases to be overlooked.—*The Journal of Tropical Medicine.*

Acid Intoxication Sui Genesis.—J. Dreschfeld and F. Craven Moore classify acid intoxication as follows: (1) The diabetic form; (2) the secondary form; (3) the cryptogenetic form or acid intoxication *sui genesis*. Each form presents many degrees of intensity, from the transient and symptomless acetonuria through the types in which acetonuria and diaceturia are associated with such manifestations as headaches and drowsiness, to the most intense comatose and often fatal types familiar in the coma of diabetes. The bulk of the observations relating to the human subject have dealt with diatetic intoxication or coma, and all with morbid conditions—diabetic or non-diabetic—which have been associated with the excretion of B-oxybutyric acid and its derivatives acetoacetic acid and acetone. There is general agreement among the best authorities as to the principal manifestations, with variations in intensity, and in the majority more or less marked gastrointestinal disturbance had preceded the outset of the symptoms of acid intoxication. Disturbance of gastrointestinal function preceding the outset of the intoxication is a common feature, and doubtless must be of significance in initiating the disturbance of metabolism leading to the apparance of "acetone bodies" in the urine. It is hard to estimate the precise rôle of these alimentary disturbances. There is considerable evidence to show that acetone is a frequent, if not a constant, urinary constituent in healthy individuals under normal diabetic conditions. It has been suggested that the acetonurias of starvation and of gastrointestinal disease are but the expression of carbohydrate starvation. The source of B-oxybutyric acid in the organism has been the subject of no little discussion. To what extent the phenomena, associated with the urinary manifestations of defective disassimilation of B-oxybutyric acid, and hitherto accepted as those of an acid intoxication, do depend upon dealkalization of the tissue fluids requires further elucidation. The hypothesis of acid intoxication undoubtedly affords a useful working basis, but there remains many collateral factors to be brought into line before it can be regarded as established. —*The Medical Chronicle.*

Points of Resemblance between Paralysis Agitans and Arthritis Deformans.—William G. Spiller reports this remarkable case. The patient was a married woman of fifty-nine years. Twelve years before admission to the hospital her neck became rigid, and she had been unable to straighten it since that time. She had suffered no pain from it. She said that the rigidity developed after she had washed her hair and sat in a draught to dry it. The lower limbs were atrophied, the atrophy being conspicuous on the thigh of each side, but was masked by œdema in the leg below the knee on each side. Considerable crepitation was obtained in each knee. The patient had a coarse tremor involving all parts of the right upper limb. This tremor sometimes ceased when the limb was at rest, but not always, and at times the tremor was partly arrested by voluntary movement of the hand. The tremor was suggestive of Parkinson's disease. There were no fibrillary tremors in the upper limbs or trunk. There was marked kyphosis at the cervico-thoracic junction. Voluntary movement of the spinal column was greatly restricted in all directions. The post-mortem examination showed decided kyphosis, the most prominent part being about the cervico-thoracic junction, also some scoliosis. Some atrophy of the shoulder muscles was seen. The fingers of both hands showed contractures, which were more marked in the right hand. There was marked ulnar deviation of the fingers, from metacarpophalangeal articulations. The feet were in the position of equinovarus, and equinocavus was decidedly greater on the right side. Had there been no tremor of the right upper limb typical of paralysis agitans, many would doubtless have accepted the diagnosis of arthritis deformans, but the tremor was so striking that some called it paralysis agitans without any reference to arthritis deformans. The writer believed that this patient probably had paralysis agitans associated with arthritis deformans, but he thought it possible that the tremor might be caused by irritation of the motor cervical roots by disease of the vertebræ. He believes that a study of the two diseases in their points of resemblance to one another may throw light on each. The pathology of each is most obscure.—*University of Pennsylvania Medical Bulletin.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51, FIFTH AVENUE.

New York, Sept. 17, 1904.

THE VALUE OF LEUCOCYTOSIS IN THE DIAGNOSIS OF INTRAABDOMINAL SUPPURATION.

SINCE the publication of Curschmann's well-known work in 1901, the study of the behavior of the blood in the presence of suppurative processes has been widely extended. Previous to this time, the changes noted in the blood were viewed with a purely theoretical interest, and to Curschmann must be given the credit for formulating conclusions based on actual observation which have come to be regarded as of great practical importance in determining therapeutic measures and establishing a prognosis. Investigation has been mainly pursued along two lines—the study of leucocytosis and the glycogen reaction, or, as the latter may be more properly designated, the iodophilia of the white blood cells. Iodophilia of the leucocytes, however, has not been regarded with much favor, as the views with reference to its prognostic and diagnostic value vary within wide limits, and the technical difficulties are much greater than those involved in the mere counting of the leucocytes.

The term leucocytosis as at present employed, is intended to refer to a transitory increase of the white blood cells, and to it must be ascribed a merely symptomatic significance. Only the absolute number of leucocytes can be taken into consideration as having any direct bearing on the diagnosis; the relative proportion between the red and white cells is of no value. It is essential, therefore, to count the leucocytes in every individual case, but the physiological leucocytosis which occurs during digestion, pregnancy, and a number of other conditions must always be taken into account when pathological processes are present.

Virchow was of the opinion that whenever glandular irritation was present, a leucocytosis resulted. This idea was soon discarded when it was discovered that certain diseases like typhoid fever were accompanied by a leucopenia rather than a leucocytosis. It is now a matter of common knowledge that there are very few inflammatory processes which are not accompanied by a leucocytosis, and for this reason the phenomenon possesses little value as a means of differential diagnosis as claimed at one time by Limbeck. The question at the present time hinges not only on the increase, but on its degree, and one is led to ask whether a leucocytosis of from 22,000 to 25,000 always denotes the presence of an abscess as stated by Curschmann. This is apparently contradicted by reports of even greater numbers being associated with severe hemorrhage, pregnancy, and other conditions. Pneumonia, sepsis, erysipelas, polyarthritis, and inflammations of the serous membranes are known to bring on a well-marked leucocytosis. Bearing this in mind, can it still be claimed that intraperitoneal suppuration is characterized by abnormally high leucocyte values? Rudolf Türkel, in a very complete critique on this subject (*Centralblatt für die Grenzgebiete der Medizin und Chirurgie*, August 5, 1904), believes that a negative answer must be returned to the question at least in this form. The numerous extraneous conditions which are liable to bring about a leucocytosis must be carefully excluded before its presence can be taken to denote suppuration, even in a clinically characteristic case. Curschmann's observations were directed entirely to the question of inflammatory processes in the cæcum or appendix, the extent of the leucocytosis being in a definite relation to the anatomical changes in this region. These observations were soon confirmed by a number of other investigators, and the results of their researches may be summarized as follows: If an exudate is purulent, no matter whether it exists in the form of a circumscribed abscess, or of a diffuse suppurative peritonitis, a leucocytosis of over 20,000 is present. This must persist for several days, however, and a single observation is not conclusive. In appropriating these results for diagnostic purposes, it is quite thoroughly agreed that clinical signs must be given their full value. A negative outcome, however, is admitted to prove neither the absence nor the presence of suppuration. It is a matter of record that when abdominal abscesses are firmly encapsulated, no well marked leucocytosis is present. This phenomenon can be explained only by a study of the circumstances which influence the production of a leucocytosis. Numerous investigations have been conducted with reference to the site and the manner of infection, but in this connection individual predisposition is evidently of the greatest moment. The appearance of a leucocytosis as a phenomenon of reaction is naturally dependent upon the ability of the body to react. In a weakened, marantic organism, the ability to combat the infection and to produce a reaction is either absent or diminished.

It appears reasonable to assume that the appearance of a leucocytosis may be traced to chemotaxic influences which manifest their effects on the hæmatopoietic organs. It has been shown that there are a large number of substances which, when injected into the circulation, bring about a leucocytosis, these including not only drugs but bacteria and their products. If we apply this knowledge to the topic under discussion, it signifies that when toxins from an abscess are absorbed by the circulation, a leucocytosis results, provided, of course, that the inherent powers of the organism to produce a reaction have not been affected. When the abscess is surrounded by a dense capsule, absorption is more or less completely prevented, no chemotaxic action is developed, and no leucocytosis is produced. But even here the leucocyte curve is of value. At the beginning of the attack it will be noted that the number of leucocytes is

increased considerably, and as encapsulation proceeds, the number sinks but does not reach normal figures. Operation in cases of this class is often undertaken too late, and when done, an abscess cavity is found filled with old stinking pus. The patient's chances would have been much better if timely operation had been instituted.

From what has just been said, it is evident that a negative leucocyte count—that is, the finding of normal, or only slightly increased, values—should not be taken as contradicting the diagnosis of abscess. The consensus of opinion among most observers, however, is that a positive result affords a more certain indication of the presence of suppuration than any one other clinical sign. This applies in particular to intraperitoneal suppuration originating in the appendix or the cæcum. The effect of suppuration in other parts of the body has also been studied, but apparently the reaction of the peritoneum to irritants is more rapid and well marked than that displayed by the remaining tissues. Whether serous surfaces, such as the pleura, have similar properties, is still undetermined, but in the case of the peritoneum it is definitely proven.

The question as to the advisability of operating in any given case of appendicitis is unsettled in many minds, and the controversy as to whether the treatment of the disease comes within the domain of the physician or that of the surgeon is not fully decided. The pendulum has swung in both directions. In every case in which the presence of an abscess can be diagnosed with certainty, only one method can be considered, and that is surgical interference. Dieulafoy's assertion that it amounts to actual crime not to turn over every case of appendicitis to the surgeon for treatment, is overdrawn, and contrary to general experience. Although Curschmann's discovery is of undoubted value, caution must be exercised in drawing conclusions from the presence of a leucocytosis in any given case, and the therapeutic indications should be based on the combination of all the clinical signs taken together. In doubtful cases, however, the critical application of this procedure may confirm the possible diagnosis of abscess, and then this phenomenon may serve to point the way for a modification of the manner of treatment. Briefly stated, the following factors must be taken into consideration in applying this procedure in order to make it of value: (1) Contributory causes which may produce a leucocytosis must be carefully excluded; (2) Repeated leucocyte counts should be made; (3) A positive result comprises leucocyte values of from 20,000 to 25,000, taken in connection with involvement of the peritoneum; (4) A negative result must never be taken as negativing the presence of a suppurative process.

Combined Degenerations of the Spinal Cord.—Pierre Marie, in his "Leçons sur les Maladies de la Moëlle," considers it probable that the combined degenerations of the spinal cord have a vascular origin, for the sclerotic changes are often found in the immediate neighborhood of the vessels of the posterior and lateral tracts, *i.e.* round the branches of the posterior spinal arteries. The direct pyramidal tract is not infrequently healthy, while the other tracts are involved; in such cases the lesion is limited to the territory of the posterior spinal arteries.

RHEUMATOID ARTHRITIS AND ITS RELATION TO SOME DISEASES OF THE GASTRO-INTESTINAL TRACT.

Dr. R. Llewelyn Jones published a paper in the *Liverpool Medico-Chirurgical Journal* of June, a part of which is taken up with this subject. In discussing rheumatoid arthritis and its relation to other diseases, it seems advisable to Dr. Jones (1) to take cognizance of those diseases which apparently are casually related to, *i.e.* share in the production of that symptom-complex which is termed rheumatoid arthritis; and (2) to ascertain the nature, if any, which appears to exist between rheumatoid arthritis and certain diseases, such as tetany, Raynaud's disease, and Graves' disease. Dr. Jones confined his attention to one group of the numerous diseases which are apparently etiologically related to rheumatoid arthritis—the gastrointestinal disorders.

The writer then referred to some cases under his care lately, and in which some obscure relationship appeared to exist between the primary gastrointestinal disorder and the succeeding rheumatoid arthritis. He based the assumption on the facts: (1) That the gastric disorder existed for some time before rheumatoid swellings appeared. (2) The onset of joint conditions was in all cases gradual, and not suggestive of microbic infection. (3) Certain prodromal symptoms were present in all cases before joint swellings appeared. (4) Any remission or exacerbation of gastric malady was correlated with a similar change in the joint conditions. The prodromal symptoms which supervened during the period intervening between the onset of the gastric malady and the appearance of periarthric swellings were of this nature, namely: (1) Recurrent attacks of local syncope and asphyxia in the extremities. (2) Muscular cramps, affecting mainly the muscles of the extremities, and in others, more widespread, involving muscles of the head and neck, and suggesting tetany. (3) Pains of definite lines of distribution. In some of the cases the muscular cramps were the most prominent symptom, in others the vasomotor phenomena, suggesting comparison with tetany on the one hand and Raynaud's disease on the other.

Dr. Jones argues that there is little clinical difference between a paroxysm of tetany with its attendant vasomotor phenomena and a paroxysm of Raynaud's disease with its associated muscular cramps. In fact, the writer is of the opinion that these superficial differences indicate a profound resemblance, as they are both probably dependent upon some similar underlying condition, *i.e.* a cerebrospinal toxæmia. Again, the tendency of these two diseases to develop along the same lines is notable. Periarthric swellings certainly occur in tetany, and Weiss and others have reported similar joint swellings complicating Raynaud's disease.

"Thus," Dr. Jones goes on to say, "in these three diseases, Raynaud's disease, tetany, and early rheumatoid arthritis, we find three sets of symptoms common to all—vasomotor phenomena, muscular cramps, and periarthric swellings—and the differentiation of them clinically depends upon the prominence of one or other of them." Therefore the author has been led to think that these three diseases may pass insensibly into each other as members of one family group, owning one common

parent origin, a cerebrospinal toxæmia. He believes, from a review of the pathological data afforded by the class of diseases known as "toxic scleroses of the spinal cord," that rheumatoid arthritis, like these chronic toxæmias in their later stages, tends to pass, into that gloomy region of medicine consecrated to system diseases of the cord. At first all its features are periodic and ephemeral, but later on, degeneration takes the place of functional nervous derangement.

With reference to the association of Graves' disease and rheumatoid arthritis, Dr. Jones published some time ago a series of fourteen cases of rheumatoid arthritis, showing in addition the four cardinal symptoms constituting the complete type of Graves' disease, the large majority of which cases there were as well in vasomotor phenomena and muscular cramps, while in one hæmoglobinuria was present. The author likewise gave a list of what appeared to be larval forms of Graves' disease coexisting with rheumatoid arthritis. After having pointed out that opinion as to the part played by the thyroid gland in Graves' disease is still divided, Dr. Jones gave it as his belief that when one sees this intimate fusion of these two diseases, one cannot refrain from asking oneself whether these two diseases when fused together are not extensions of one and the same morbid process, a cerebral spinal toxæmia.

The good effect of thyroid feeding in cases of rheumatoid arthritis is then referred to, but valuable as thyroid feeding may prove to be, the writer holds the view that it should not, if we consider rheumatoid arthritis to be in the nature of a toxæmia, allow us to be turned aside from the ideal line of treatment—radical, and if necessary, surgical treatment of any ascertained source of toxæmia.

Dr. Macalister, who read a paper on the same subject a short time ago, expressed opinions which, in the main, were the same as those of Dr. Jones, and pointed out that no source of chronic toxæmia, whether situated in the oronasal cavities or in the gastrointestinal, respiratory, or genitourinary tract, if recurrent local asphyxias and muscular cramps are met with, should be dismissed lightly, but rather these disturbances should be regarded as possible premonitory symptoms of rheumatoid arthritis.

With regard to the infective theory of rheumatoid arthritis, Dr. Jones does not believe that specificity can be claimed for one particular microbe, but is of the opinion that, given any source of autointoxication, the resulting toxæmia may, through its action on the cord segments, produce what is called rheumatoid arthritis.

Nervous School Children.

Dr. C. C. Krauskopf, assistant supervisor of the child study department of public schools of Chicago, has prepared statistics which show that one-third of the school-children of that city are afflicted with some form of nervousness, mild or aggravated. Some of the pupils examined exhibited signs of mental depression with a marked tendency to melancholia. Others presented choric symptoms. The prevalence of nervous disorders among children is attributed to the following causes: Strenuous city life; impure city atmosphere; the bringing up of children in flats, no relief from noise, day or night; lack of proper nutrition; late hours permitted by parents, and residence along cable and trolley car lines. The finding is based on statistics collected in every part of the city.

The announcement sounds a timely warning and calls for the earnest consideration of school authorities and parents. Undoubtedly a large part of the nervousness of the school-children is due to the peculiar conditions imposed by life in the city. From the hour he awakens until he goes to sleep at night, the average resident of almost any of the larger cities in this country suffers a severe strain upon his nervous strength. The process continues even when the victim is least conscious of it. Another factor in the depreciation of nervous health is found in the fact that in many homes the best and most nourishing foods are omitted from the daily bill of fare or are improperly cooked. Add to these hurtful influences a hard mental application required in the school-room, in an atmosphere often vitiated and amid the incessant rustle caused by the presence of many restive children, and we have conditions, Dr. Krauskopf believes, admirably adopted to produce a population of nervous dyspeptics.

There is an obvious need for the betterment of the living conditions, both in homes and in the public schools. School boards must recognize the fact that no amount of learning can fit children for the duties of life if they are to reach maturity with poor health and disordered nerves, and they must therefore take measures to insure better ventilation of school-rooms and protect the pupils against undue nervous tension.

Prevention of Postoperative Intestinal Paralysis.

Pankow recently made some comparative observations to determine the value of physostigmine as a preventive of postoperative meteorism. The observations were made at the Frauen Klinik in Jena (*Zentralblatt für Gynäkologie*, No. 31, 1904). All the patients were treated the same, and were given a rectal enema of plain water on the evening of the second day, or even earlier if troubled with gas. It was found that meteorism did not occur in any case within the first four hours after a laparotomy or the Alexander-Adams operation, but came on quite often after the vaginal operation within this same length of time. It was also observed that when intestinal adhesions had been present, the motor functions of the gut returned much earlier than in the other cases. The length of the operation or the narcosis seemed to exert no influence. In comparing the untreated cases with those treated with injections of physostigmine after the operations, it was found that very little difference existed, and no favorable influence could be ascribed to the drug. Pankow believes that postoperative paralysis of the gut may be largely prevented by the preliminary preparations and the handling of the intestine during the operation. If possible, the gut should not be turned out of the abdominal cavity. Patients are allowed full diet until noon of the day previous to operation. For supper on that day they are permitted only a plate of soup, and nothing is given the next morning unless the operation is delayed, when coffee is allowed. Purgation is not permitted. When obstinate constipation is present, caster oil (½ ounce) is given on the morning of the day before the operation. All patients receive a soap-suds enema the evening before operation. With these precautions

Pankow claims that the operation will not be interfered with by distended intestines and that the patients will be in better condition to stand operation.

THE -IC TIC.

Although several medical journals, including the official organ of our national medical organization, are given over to the *-ic* habit, or the sin of substituting the termination *-ic* for *-ical*, the ugly apocope is not patiently accepted by all medical writers and readers. We are not infrequently called upon for an opinion regarding this mutilation, and often urged to protest against it, and one American correspondent not long since appealed to the editor of the *British Medical Journal* for an opinion on this linguistic innovation. The editor referred the question to Dr. Henry Bradley of Oxford, whom he calls one of the highest authorities on such subjects.

Dr. Bradley, after discussing the reasons for bringing back the discarded *-al* in the formation of the adverb (as *pathologically*), says of the main question: "When there is a pair of related adjectives in *-ic* and in *-ical* they are usually in most contexts so precisely synonymous that the choice between them is left open, though usually one of them is more common than the other. But often there are certain particular contexts in which usage absolutely requires the one and not the other. In adjectives connected with the name of a science there is a tendency, by no means universal, to use the longer form to express the notion of 'pertaining to the science itself,' and the shorter form to designate things that are part of the subject matter of the science. Thus we prefer to speak of '*geologic* periods' but of 'a *geological* treatise,' '*Historical* works' are works treating of history; if we said '*historic* works' we should be understood to mean works which were themselves facts in the history of the race. If there is to be any yielding to what you describe as the American innovation of substituting the shorter for the longer form, I think it would be well to try to follow the lines of the existing distinction above indicated. That is to say, if we do use *physiologic*, let it be used only to mean 'forming part of physiology considered as a body of fact,' and let us continue to use *physiological* when we mean 'pertaining to the science or study of physiology.' Thus we might speak of '*physiologic* phenomena' but of '*physiological* treatises or theories.' Of course, very often the two meanings so run together that on this principle it would not practically matter which word was used. Still, I can imagine that the establishment of such a distinction might occasionally tend to lucidity. I am not particularly recommending the American practice; I am only suggesting a way in which, if it becomes prevalent, it might perhaps be turned to useful account."

There is, it must be admitted, a tendency in the English language to drop the final *-al* in all these adjectives—one no longer says diagnostical or characteristical, for example. And it must also be recognized that it is vain to oppose the corruption of language beyond a certain point, but it is not therefore necessary to accelerate the change by prematurely adopting such a cacophony as *chemic*. We may all be medic or surgic practitioners in time, but we hope not soon.

Genu Valgum.—The proper treatment is osteotomy in accordance with the rules laid down by Macewen and Schede.—ABERLE.

News of the Week.

The Seventh International Congress of Otology was held in Bordeaux, August 1-4, under the presidency of Dr. Moure of that city. Set discussions were had on "The Diagnosis and Treatment of Labyrinthine Suppuration" by Drs. Brieger of Breslau, v. Stein of Moscow, and Dundas Grant; and "Operation and After-Treatment of Otogenic Abscesses of the Brain" by Drs. Knapp of New York, Schmiegelow of Copenhagen, and Botey of Barcelona. The next congress will assemble at Budapest in 1908.

Hospital for Contagious Diseases in East St. Louis.—The Good Government and Improvement Association of Belleville, Ill., has appointed a committee to appear before the county board of supervisors and petition the board to supply a sufficient number of nurses for the contagion hospital. The committee will also urge the board to appropriate a sufficient sum to erect a contagion hospital at East St. Louis, so as to obviate the removal of patients from that city to Belleville to take care of the surplusage of patients from the county at large and for the special care and treatment of patients in East St. Louis. The association passed a resolution to assist the county financially in supplying nurses for the contagion hospital and also in erecting a contagion hospital at East St. Louis.

A Town Sued for Establishing Quarantine.—The Hoosac Valley Street Railway Company threatens to bring suit against Williamstown, Mass., alleging that the latter unlawfully quarantined North Adams and kept North Adams people out of the town because of the smallpox epidemic. The company claims its business was damaged several thousand dollars. The same action may be taken against Adams, but there the quarantine was not so strict. Officers mounted cars in Williamstown and prevented every one from landing in the town.

Sale of Carbolic Acid Restricted.—At a recent meeting of the Board of Health of New York City, the following amendment was made to the Sanitary Code: "No phenol, commonly known as carbolic acid, shall be sold at retail by any person in the city of New York, except on a prescription of physician, when in a stronger solution than 5 per cent."

Milk Sickness in Illinois.—The Illinois State Board of Health has instituted a systematic study of this disease which has reappeared after having, as it was believed, died out many years ago. Four deaths from milk sickness have recently been reported. It was formerly thought to be contracted by the ingestion of the flesh or milk of cows with the "staggers."

Dr. Thomas E. Bamford, who has been chief of staff at the Hudson River State Hospital for a number of years, has resigned his position, to take effect October 1, and will engage in general practice in Syracuse.

Inspector of Contagious Diseases Appointed.—As a result of the typhoid epidemic in the Bronx, a new office has been created by the Board of Health, the incumbent of which will be known as "Chief Inspector of Contagious Diseases in the Bronx." Dr. Charles F. Spencer was appointed to the office. He will make his headquarters at 168th street and Franklin avenue.

Another Ambulance Wrecked by a Car.—As an ambulance of the Bushwick Central Hospital, Brooklyn, was passing along Reid Avenue to answer a call on Saturday evening it was run down and wrecked by a trolley car. In the ambulance, besides the driver, were Dr. Huyser and a policeman.

All were thrown out. The driver was the worst injured; two of his ribs were broken. Both of the others, however, were cut and bruised. Dr. Huyser dressed the driver's hurts and attended to the policeman, whose wrist was sprained, and then went to the hospital to have his own hurts attended to. This is the fourth or fifth accident of the kind which has occurred in this city within a year.

Copper as a Germicide.—The chemist of the Department of Agriculture is experiencing the lot of all great personages in failing to receive honor in his own home. According to the newspapers, he has purified the water supply of very many cities and small towns in this country by swinging a bag of blue vitriol in the reservoir, but now that Washington itself is threatened with a typhoid-fever epidemic, the health officer will not permit its water to be impregnated with copper salts, and the agricultural chemist is in despair.

Sydenham Hospital Charges Dismissed.—The State Board of Charities has dismissed the charges against the trustees of the Sydenham Hospital, of New York, on the grounds that the institution, not receiving any public funds, is not under its jurisdiction. It has been suggested to the complainants that the conditions complained of can be corrected through the Supreme Court.

Boorish Treatment of Scientists.—The Society of Chemical Industry, which met in international session in this city last week, was entertained by the local chemists at a banquet at which it was expected that the Mayor of the city would be present to welcome the visiting scientists. But that functionary neither appeared himself nor sent any one to represent him. The present mayor, unlike some of his predecessors, knows what is decent in the matter of human intercourse, and so his snub to the distinguished visitors cannot be excused on the score of ignorance.

Dr. William Lord Smith of Worcester, Mass., according to a report from that city, has received the honorary appointment of physician in ordinary to the Shah of Persia. Dr. Smith, it is said, was caught at Ispahan during an outbreak of the plague. He was detained much against his will in quarantine, and while on his enforced visit prescribed for the natives with great success. About this time the Shah came down with malaria, and hearing of the wonderful American and his marvelous cures, sent for him. The invitation was a command, and Dr. Smith made the 210-mile trip on a camel. He cured the Shah and the G. P. made him physician in ordinary and urged him to remain at the court permanently.

First Aid Pupils Save a Life.—Two policemen found a man who is a pipe fitter for one of the gas companies, sitting motionless at the bottom of a street excavation, his head bowed upon his breast. One of the policemen leaped down and passed the man up to the other. The man was unconscious but the policemen applied artificial respiration until an ambulance from Roosevelt Hospital arrived half an hour later. The man was finally resuscitated, and the ambulance surgeon told him he owed his life to the policemen.

Gift to St. Luke's Hospital, Chicago.—According to the will of Mrs. J. H. McVicker, $10,000 will be given to this institution.

Drs. B. B. Griffith and James L. Taylor were recently appointed members of the Springfield, Ill., Board of Health.

Dedication of Washington Park Hospital.—A hospital bearing this name, located at 6010 Vincennes avenue, Chicago, was formally dedicated September 5. The staff includes Drs. John B. Murphy, Frank Billings, Archibald Church, Wm. A. Evans, and Alfred Hakanson. The chief of staff is Dr. C. O. Young.

Dr. Follen Cabot, Jr., of New York has been appointed genitourinary surgeon to the City Hospital.

Duty on Radium.—An appeal against the assessment of a 25 per cent. ad valorem duty on radium was argued a few days ago before the United States general appraisers by Hugo Lieber, a chemist of this city. Radium has been assessed the duty named, as a chemical compound, but Mr. Lieber took an appeal from the decision on a recent importation, contending that it should be entered free as a crude mineral.

The New York State Veterinary Medical Association held its fourteenth annual meeting in Brooklyn on September 13, 14, and 15. The meeting was largely attended. The following officers were elected for the ensuing year: *President*, Dr. George H. Berns of Brooklyn; *Vice-President*, Dr. Charles Corvie of Ogdensburg; *Secretary-Treasurer*, Dr. William Henry Kelly of Albany.

Rabies in Ithaca.—Health Officer Crum of Ithaca, N. Y., has asked help from the State Health Department to control a threatened epidemic of rabies which has been developing there for the last two weeks. A mad dog ran amuck through the city some time ago, and bit many other dogs before he was caught. Several persons have also been bitten by supposed rabid dogs, but as yet no case of human rabies has been reported. Inoculation experiments showed that the dog, with which the epidemic is believed to have originated, was suffering from virulent hydrophobia.

A Case of Alleged Maltreatment in a State Hospital.—A Coroner's jury of eight physicians and four laymen in the inquest to determine what led to the death of a patient in the Manhattan State Hospital, May 1 last, has returned a verdict that the man's injuries were not self-inflicted, and has recommended that an investigation be made by the Grand Jury. An autopsy performed on the man's body soon after he died disclosed the fact that eight of his ribs were fractured, that both of his eyes were blackened, and that he had contusions on various parts of his body.

Obituary Notes.—Dr. Edward Payson Buffet of Jersey City died of disease of the heart on September 9, in his seventy-first year. He was born at Smithtown, Suffolk county, L. I., on November 7, 1833. He was graduated from Yale in 1854 and from the College of Physicians and Surgeons in this city three years later. He moved to Jersey City in 1858. He was for many years a visiting surgeon at Christ Hospital and surgeon at the City Hospital.

Dr. William L. Buechner of Youngstown, Ohio, was killed on September 10, by being thrown over an embankment in a runaway accident. He was a graduate of the Medical Department of Western Reserve University, Cleveland, in 1885.

Dr. John L. J. Gormly of Brooklyn died on September 6, of disease of the heart, at the age of twenty-nine years. He was graduated from the Long Island College Hospital in 1897.

Dr. John T. Brosnan of Brooklyn died at his home in that borough on September 9. He was a graduate of the Bellevue Hospital Medical School in 1893.

Dr. John Lyle Campbell, dean of the Wabash College faculty, died at his home in Crawfordsville, Ind., on September 7. In 1868 Dr. Campbell, conceived the idea of celebrating the centenary of American Independence and wrote Mayor McMichael of Philadelphia concerning it. The suggestion was taken up and resulted in the Centennial Exposition.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

SCIENCE AT CAMBRIDGE—THE NERVOUS SYSTEM—PLAGUE—HELMHOLTZ'S THEORY—PROPERTIES OF MIXTURES—HEREDITY AND VARIABILITY OF SPECIES—DEGENERATION—RADIOACTIVITY.

London, August 26, 1904.

The Scientific Congress has come to its close. Mr. Balfour presided at the final meeting and the members have dispersed. A great amount of work was got through, as only a few items will show. Professor Sherrington opened the section of physiology with an address on three points of view from which the science studies the nervous system. First, its processes of nutrition, which can be followed in nerve cells as well as in others, but nerve cells have certain specialized functions, such as the power to transmit excitements. This power, which is called conductivity, is the object of the second problem. The third is the way in which by this conductivity the cells and units of an animal are welded into a whole, forming from a collection of organs a single animal. It was this last point to which the president directed the chief attention of the section.

To this section belongs the credit for industry, as on Saturday, when the others were dispersed over the neighborhood in search of recreation, the physiologists stuck to work all the morning, when Dr. Hankin gave his reasons for holding that the plague in India in 1896 was spread by fakirs on their way to the festival at Nassik from Garwhal, where it was endemic, and other outbreaks were probably produced in the same way. Dr. Hankin considered fleas, which are always at home on these fakirs, as the direct agent of communication.

Dr. C. S. Myers read a paper on the recent development of Helmholtz's Theory of Hearing. A pure tone sounding in a series of wires, set in vibration not only the wire attuned to that rate of vibration, but also others which were its simple multiples, thus giving an explanation of the resemblance of a note to its octave, and next to that the fifth, and after that the fourth. Assuming this, it explains the fact that two notes of nearly the same rate of vibration reinforce each other, producing a fused sensation of an intermediate tone, but if the rates of the two tones differ more the resulting fused sensation is discordant.

In the Chemical Section Prof. Sydney Young's presidential address was a review of the state of our knowledge of the properties of mixtures. He outlined the methods of investigating the behavior of liquids when mixed together as to (*a*) their miscibility, infinite, partial, or inappreciable; (*b*) the relative volumes of the mixture and its components; (*c*) the heart evolved or absorbed.

The Zoological Section, from all one hears, seems to have been the most successful. The president, Mr. Wm. Bateson, F.R.S., opened it with an address, the "facts of heredity and of variability of species as exhibited by the practical examination and experiment of breeding." He said the breeding was to the zoologist what the test was to the chemist. Darwin's work brought the origin of species within the grasp of our intelligence, but as his theory required the lapse of enormous periods of time men turned their attention to investigations within the limits of human life. After examining the theories of De Vries, Mendel, etc., the president said nature seemed to exercise selective operations as potent as those which man employed in breeding experiments. The corollary to Virchow's aphorism that every living cell sprang from another, was that every variation from the type is "founded on a pathological accident." He then stated the limitations of the knowledge of heredity, and added there are those who look to it with lofty aspirations and ask if the science can be used to make those who come after us healthier, wiser, or more worthy. "The answer," he said, "is No, almost without qualification. We have no experience of any means by which transmission may be made to deviate from its course; nor from the moment of fertilization can teaching or hygiene or exhortation pick out the particles of evil in that zygote or put in one particle of good. Education, sanitation, and the rest are but the giving or withholding of opportunity." You will not be surprised after this that the debate on heredity fixed for the next day was most animated. The battle, for so the discussion is spoken of, has in fact been fought before, e.g. at the Linnean Society—but scarcely with the intensity with which it was waged at Cambridge. In fact, the debate is declared by many to have been "the big thing of this year's meeting."

In the Anthropological Section Mr. Balfour took part in the debate on degeneration, and asked how would medical men analyze the effects of town life? Food was better than it used to be, education better; where is the difference between workers in town and in country? Was it a question of ventilation in the home or air in the streets? If theories of heredity were true, only processes of elimination could affect the race, but the tendency was for families to become smaller among the well-to-do. Everything which opened every career to everyone of ability tended to the deterioration of the race. Permanent causes could not be affected in a life-time by legislation. Dr. Shrubsole said city life tended to eliminate tall, fair-haired, and leave townspeople with dark and red-haired people.

In the Mathematical and Physical Section radioactivity was the subject of a discussion from which much was expected but scarcely realized, and the president (Professor Lamb), in summarizing, observed jocosely that enough had been said to suggest that "one speck of radium makes the whole world kin." The discussion, however, was memorable from the acceptation by Lord Kelvin of the disintegration of the atom as the cause of radium activity—a theory which last year he opposed.

At the closing general meeting of the association Mr. Balfour again presided. One thousand pounds was granted for research by sections. Arrangements were announced for next year's meeting in South Africa. Prof. George Darwin of Cambridge has been elected president for that meeting.

AN OLD-TIME DOCTOR.

To the Editor of the Medical Record:

Sir: I saw awhile ago, in the Medical Record, a short sketch of an old-school doctor, and thought perhaps you might like to hear of another.

Dr. Ezekiel Skinner was born in Glastonbury, Conn., June 27, 1777. His mother died when he was five years old, and his father when he was ten. Thus early an orphan, he was consigned to an uncle, who, when he had reached a suitable age, apprenticed him to the trade of a blacksmith. But all his father's family having died of consumption, he resolved to study medicine and see if he could find some way to arrest the disease. He bought the last year of his apprenticeship and spent it in attending school. He then commenced the study of medicine under the direction of Doctor, afterward Governor, Peters of Hebron, Conn., where he remained three years. He then obtained the means for going to Philadelphia to complete his medical studies with Dr. Rush. He received his license to practice medicine in 1801, and was married the same year. He first settled as physician at Granville, Mass. Ian MacLaren's description of the doctor of Drumtochey would answer for this man. In 1812 he enlisted as a soldier in the war, but his medical worth was soon discovered and he was transferred from the ranks to the hospital.

One of his sons went as missionary to Africa, contracted the fever prevalent in that climate, and died on the voyage, while trying to reach home. His father said he *knew* he could cure that disease, and although then sixty years of age, he left a good practice to go to Liberia. He took the fever, but had it lightly. On his arrival at Monrovia, being very weary, he retired early, but before getting to sleep a messenger called where he lodged, and asked for the new doctor, saying a man in the neighborhood was very ill and could not live till morning, unless relief was procured; that his physician had given him up to die. He was told that the doctor had just arrived, had not passed through the acclimating process, and his life would be endangered by going out in the evening air. But Dr. Skinner, hearing the conversation, rapped on the floor and directed them to detain the messenger till he could dress, and he would go under his guidance to see the patient. His going was the means of saving the life of the man, who was very sick and, in addition, suffering from malpractice. The patient was George Pinney, afterward Governor of Liberia. Dr. Skinner remained there about three years, and for some time was acting governor of the colony. As a student under Rush, he imbibed many of his opinions, and for the cure of many, if not most, diseases relied mainly upon calomel and the lancet. Predisposed from his youth to consumption, afflicted repeatedly with hemorrhage of the lungs, he reduced arterial action by free use of the lancet, bleeding himself one hundred and seventy-five times. He was ardent, frank, cheerful, and light-hearted, and utterly fearless in the discharge of duty. He was a bold and skilful surgeon. An incident will illustrate his courage and the impetuosity of his character. While still a student, his preceptor came into the office one day and remarked, "Old Martin must die of apoplexy because we cannot get blood from him." Springing to his feet, Dr. Skinner exclaimed, "God Almighty never made the man I cannot get blood from."

and immediately went down to old Martin's house, and opened the jugular vein, got blood freely, and the patient recovered.

Near the time for his return to this country, from Liberia, Dr. Fuller, a very eminent surgeon, in company with another, remarked that he had just come from a patient suffering with a tumor, but that it was so connected with a main artery, that he did not care to encounter it, and that he did not know of any one who would have the courage to undertake the necessary operation but Dr. Skinner, and that he is in Africa. Soon after, Dr. Skinner, who had just arrived from Liberia, came in, and Dr. Fuller after greeting his friend, told him of the case, and although he had just landed in New York and was on his way to see his family after a long absence, he immediately took the stage for Middletown, found the case as described by Dr. Fuller, performed the operation with entire success, and returned home the next day.

In April, 1855, Dr. Skinner went to Greenport, to live with his son, Dr E. E. D. Skinner, where he gradually declined, though he did not desist from active service till two weeks before his death. He died on December 25, 1855, aged seventy-eight years. His son died many years ago. Two medical grandsons are living, Dr. E. D. Skinner of Mineola, and Dr. B. D. Skinner of Greenport, L.I.

One Who Knew the Old Doctor.

Progress of Medical Science.

The Boston Medical and Surgical Journal, September 8, 1904.

Spindle-cell Sarcoma of Foot, with Lung Metastases.—Charles L. Scudder relates the history of this case. The patient was a man about twenty-two years old. In April, 1903, he fell down stairs, twisting the right foot. He used crutches from the time of the accident. In July he complained of a dull, throbbing pain in the foot. An incision was made into the sole of the foot, and a large quantity of apple-tapioca-pudding-like material mixed with blood was evacuated. The material was examined, with a report of sarcoma. On August 5 the glands in the groin were removed. They were not found to be malignant. On August 8 the leg was amputated eight inches below the tuberosity of the tibia. The diagnosis of the disease was spindle-cell sarcoma. The growth apparently originated from the muscles and tendons. The patient caught cold in November, and suffered from a severe cough. He died December 20. Autopsy revealed sarcomatous metastases of the lungs. A case of spindle-cell sarcoma originating in the soft parts of the sole of the foot, is extremely interesting. The interval between the time of the accident and the death of the patient was only eight months. The writer believes that exploratory incision into malignant growths is unwise. He declares that the question may be raised in this case: Did the incision into the sole of the foot, with subsequent curetting and laceration of the veins, contribute in any way to the metastases? He concludes by saying that a very thorough examination of the body of any individual with sarcoma of the extremities should be made, to determine if possible, the existence of metastases before any radical operation is attempted.

The Interrelation of Medicine and Surgery in the Treatment of Gastric Ulcer.—Hugh Cabot and George S. C. Badger call attention to the fact that but a comparatively short time ago, gastric ulcer, both in its acute aspects and in its chronic complications, was regarded as a purely medical disease. It is admitted that the acute and subacute varieties of dyspepsia and acute gastritis are distinct medical conditions, and are not likely to have any relation to surgery. On the other hand, perforating ulcer of the stomach has long been a distinct surgical condition in which surgical intervention offers the only hope of cure. Acute attacks of hemorrhage from the stomach due to gastric ulcer are nearly always to be treated medically. The hemorrhage can generally be controlled by rest, morphine, and nutrient enemata. But there are cases in which the hemorrhage can be controlled only by surgical measures. Recurrent hemorrhage is particularly characteristic of gastric ulcer. It occurs in a large number of cases. Chronic ulcer, however, may exist for years without symptoms. The writer speaks of several classes of chronic ulcer. The first which he considers includes cases of severe chronic dyspepsia without marked dilatation of the stomach. In many cases medical treatment is indicated, but there are those in which only surgical treatment will avail. A certain number of cases, at first apparently of chronic dyspepsia, will after a while show the condition known as hour-glass stomach. Diagnosis can be made only when there is a distinct constriction forming two or more pouches. These cases should be operated on before they have developed into true hour-glass stomachs. More work must be done in this field, before the physician can always feel sure of his diagnosis. Then, again, there are the cases of chronic dyspepsia accompanied by dilatation of the stomach. If this is atonic dilatation, medical measures will suffice. If the case, however, resists medical treatment, exploratory operation is justified. As to the relation between the physician and surgeon in regard to these cases, neither alone can do justice to his patient. All stomach cases are at first in the province of the medical man, but many of them become surgical. The two must cooperate intelligently, if the best results are to be attained. The writers sum up the indications for surgical treatment as follows: (1) Perforating ulcers of the stomach. (2) Bleeding ulcers in which the hemorrhage either cannot be controlled by medical means, or, having been controlled, tends to recur, thus placing the patient's life in immediate danger. (3) Cases with a long history of dyspepsia culminating in hemorrhage, after the hemorrhage has been controlled by medical means, and the patient put in proper condition for operation. (4) Cases of intermittent recurring hemorrhage which, though individually small in amount, tend by their persistency to produce a profound anæmia. (5) Cases of chronic dyspepsia without dilatation, which fail to yield to proper medical treatment. (6) Cases of chronic dilatation of the stomach which fail to yield to medical treatment and are not due to a general visceral ptosis.

Journal of the American Medical Association, Sept. 10, 1904.

Menorrhagia in Typhoid Fever.—William Himmelsbach reports the history of a woman, thirty-five years old, with a temperature of 102.5°F. and a history of bronchitis, vomiting, and general malaise. In a few days the case was diagnosed typhoid fever. On January 20 there was a profuse uterine hemorrhage; prior to this the temperature was 103.5° F., shortly followed by a drop to 100° with subsequent rising. Bimanual examination excluded any lesion, and close questioning, and absence of characteristic odor eliminated the menstrual flow. Efforts to check the flow were futile, but, after two days, it ceased spontaneously. About the twentieth day the temperature declined to 100.2° F. and suddenly, preceded by a chill, went to 104° F. The lower lobe of the right lung was found to be pneumonic. It took the usual course and the patient was discharged some six weeks later.

The Anatomy and Radical Cure of Inguinal Hernia.—Daniel N. Eisendrath, after considering the anatomy of inguinal hernia, mentions all of the methods briefly to show how different surgeons have striven independently of each other to remedy the defects of the Bassini operation. His conclusions are as follows: In the normal inguinal canal the anterior wall is relatively stronger than the posterior. This condition is exaggerated in inguinal hernia so that the larger the hernia the greater the muscular gap between the arching fibers of the internal oblique and Poupart's ligament. In the smaller herniæ almost any of the modern operations, either with or without transplantation of the cord, will suffice. When the muscular gap is marked some method must be employed in which a strong aponeurotic structure is used to fill the gap. The Andrews modification of the Bassini operation, by utilizing a portion of the external oblique aponeurosis as an additional layer in the posterior wall of the canal, gives the latter great strength. The majority of surgeons believe best results are obtained by not transplanting the cord. It is still an open question whether or not the veins should be resected.

The Pelvic Ureteral Sheath; Its Relation to the Extension of Carcinoma Cervicis Uteri.—John A. Sampson states that the pelvic portion of the ureter is surrounded by a sheath which is apparently derived from the tissue along or through which the ureter passes, and owes its origin to the peristaltic movements of the ureter, thus causing intermittent pressure on the surrounding tissue. Near the bladder the ureter is reinforced by muscle bundles, some of which apparently come from the bladder, while others are apparently derived from the outer coat of the ureter. These muscle bundles also form a sheath about the ureter, with which the sheath previously referred to fuses. The formation of a sheath about the abdominal portion of the ureter is very imperfect and in places apparently absent, which may possibly be explained on the ground that the surrounding tissue is loose and offers little resistance to the contractions and expansions of the ureter. The inside of the sheath is filled with adipose tissue and fine strands of connective tissue in which are imbedded vessels. While this sheath protects the ureter from the invasions of inflammatory processes and new growths, at the same time the local thickening of the sheath may interfere with the function of the ureter, thus giving rise to hydroureter and renal insufficiency, and predisposing to kidney infection and helps form the thickened ureter found in cases of ureteritis. The ability of the ureteral

sheath to resist the invasion of carcinoma depends more on the nature of the growth than any quality of the sheath. The sheath is of importance in operations in the pelvis, for if the integrity of the sheath is preserved, that of the ureter is assured.

[*Medical News*, September 10, 1904.]

The Gastrointestinal Crisis of Erythema Exudativum Simulating Appendicitis.—A. M. Pond believes that gastrointestinal crises in erythema exudativum are a very important and quite a constant symptom. Osler accounts for these crises as being "probably due to localized œdema of the gastrointestinal walls," and classes these cases with those of angioneurotic œdema in which colic is such a prominent and constant feature. The writer gives the history of an interesting case of this nature. He believes that great caution is necessary in making a diagnosis of these cases which present the acute characteristic paroxysms of colic, attended by vomiting rapid pulse, a tender abdomen, with perhaps a tumor, with either a spasm of the abdominal recti muscles, or in the later stages, a condition of abdominal rigidity. Although these symptoms may appear typical of involvement of the appendix, or of other abdominal viscera, operation should not be decided upon too hurriedly. The family history must be carefully studied in relation to skin, joint, or kidney lesions. And both blood and urine examinations must be made. If the gums are spongy, bleeding easily; if there are joint symptoms, or areas of angioneurotic œdema with hyperæsthesia, an early operation is not to be recommended, unless the blood count shows a rapidly increasing leucocytosis. The examinations should be made hourly, and the increase be distinct before operation is undertaken.

Influenza in Children.—Kenneth E. Kellogg declares that influenza oftentimes runs a more protracted course in children than in adults. Besides affecting the nasal mucous membrane, the bacillus of this disease wanders into many tissues of the body. It is probable that the catarrhal symptoms are due to the presence of the bacillus itself, and the immediate effects of the toxin are shown by symptoms directly referable to the cerebrospinal center. The remote effects are seen in the lowered tone of the nervous system, and other tissues, the patient being thus in a condition in which he cannot easily resist disease. Several types of influenza have been described, such as the nervous type, the gastrointestinal type and the respiratory type. Often, there exist combinations of these types, making the various phases hard to recognize. The catarrhal symptoms are in a measure characteristic of the disease. The fever is strikingly irregular. One type of the disease stimulates typhoid fever. In the nervous type the child is peevish and irritable, while the prostration is out of proportion to the other symptoms. The gastrointestinal symptoms are vomiting and diarrhœa. Purpura often occurs, and so may œdema. The mastoid process is often involved. Acute dilatation of the heart has been noticed. Nephritis is a rare complication. A fairly common symptom is a pseudopertussis cough. The diagnosis of influenza is generally arrived at by the process of exclusion. The serious nature of this disease requires prompt and constant attendance. Cases should be isolated, on account of the communicability of influenza. If the attack is severely toxic, elimination should be stimulated. Hydrotherapeutic measures should be tried. Phenacetin is preferable to opium to allay the nervous and muscular manifestations. No measures which tend to depress the nervous system should be used. The use of strychnine is valuable. Local treatment for the nasal symptoms in the form of a saline spray is beneficial. Subacute cases are often helped by change of air. Good hygiene. The rules of hygiene should be carefully observed. Finally, the writer emphasizes the great value of prophylaxis in relation to this disease.

An Analytical Study of Twenty-eight Cases of Arthritis, with Special Reference to Gout and Its Treatment.—Charles C. Ransom calls attention to the relatively large incidence of gout which he has noted in twenty-eight cases of arthritis carefully studied by him. These cases were selected from 415 general medical cases admitted to the hospital during the months of November, December, and January of the last year. Of these twenty-eight arthritides, twelve, or 43 per cent., were gout, this being 2.89 per cent. of the total number of cases admitted. Five of these were acute podagra, while the other seven were of the chronic type of the disease. The acute cases were all classic, beginning in the metatarsophalangeal joints of the great toes with swelling, redness, and pain, which were more severe at night. A sharp initial fever was also present. These symptoms all quickly subsided under the administration of colchicum. A review of the seven cases of chronic gout shows, with possibly two exceptions, that there was no mistake in the diagnosis. The high percentage of gout cases found in this series by the writer is surprising, on account of the general idea held by observers that the prevalence of gout in this country is less than in Great Britain and Europe. Just as surprising, however, is the relatively small number of cases of rheumatic arthritis found among this series of hospital cases. Only 18 per cent. of the total number were of this class. Of these five cases, four were acute rheumatic arthritis, and only one, chronic rheumatism. There were five cases of gonorrhœal arthritis, or 18 per cent. of the total number of cases of arthritis. Only one case of septic arthritis, or 3.5 per cent., appeared, while there were two cases of erythromelalgia. Two doubtful cases were noted. There was one case of arthritis deformans in a female. As to treatment, a milk diet was ordered for the cases of gouty arthritis. The joints were painted with a mixture of oil of gaultheria, one drachm, and ichthyol, one ounce. The joints were then wrapped in cotton wool, over which rubber protective or oil silk was held in place by a roller bandage. Colchicin, $\frac{1}{100}$ of a grain was given every two hours. If this affected the bowels, it was given at longer intervals. As a rule, the inflammation and pain were controlled within forty-eight hours. After the subsidence of the acute symptoms, the drug was given every four hours. In the chronic cases, the same method was used, if there was inflammation present. Massage was employed in the case of stiff joints, and the patients were directed to use the joints as much as possible. A simple apparatus, called a "teeter" was also employed, by means of which the patient, while sitting in a rocking chair, is able to exercise the knee and ankle-joints. The writer has also found the ichthyol bath of service in chronic cases. Massage precedes the bath. Tonics are given as required. In acute rheumatic arthritis, besides the milk diet and the joint treatment, salicin is administered. Rheumatic joints should not be put in splints. In gonorrhœal arthritis, irrigation and local application of silver nitrate to the urethra are valuable. Good food and tonics should be used in arthritis deformans. Static electricity is beneficial, also, as well as the ichthyol bath.

New York Medical Journal, September 10, 1904.

Diagnosis of Influenza and Articular Rheumatism.—Max Talmey gives the typical symptoms of both these affections, and points out the fact that the two diseases seem so well-defined that they could hardly be confounded. Yet if the so-called "rheumatoid" form of influenza and the cardiac complications be considered we find that influenza may present a picture similar to and difficult to distinguish from acute rheumatism. In both diseases we have the main symptoms, fever and the involvement of the joints and heart. The character of the fever and heart affection may be alike in both, but the affection of the joints affords us differential points. In rheumatism the joints are swollen, red, and hot; in influenza they are not. In rheumatism the seat of pain is in the joints themselves, while in influenza it is in the muscles and their attachments. Slight passive motions in the joints considerably increase the pain in rheumatism; but very little, or not at all, in influenza. Other differential points are the spontaneous sweats and the family predisposition in acute rheumatism, while in influenza we have the protracted convalescence with nervous heart disturbances.

The Treatment of Mucomembranous Colitis by Colostomy.—John M. Elder reports a case which is interesting by reason of its long duration, notwithstanding careful medical treatment, and the apparently complete cure obtained as the result of surgical interference. He also gives a retrospect of the literature on this subject, showing the marked advance made in this special line of surgery. From left-sided inguinal colostomy a step was made when the whole colon was put at rest by an operation done on the right side, and this seems to be the better operation. The Kader-Gibson and Weir methods are ingenious ways of affording means to irrigate without inconvenience to the patient, permitting him to continue his occupation and promising a cure. The Weir method can readily be seen to be applicable only to those cases in which the appendix is freely movable and is long enough to be brought to the surface and utilized as a drainage tube. The older and oft tried method of right inguinal colostomy seems to suit well in the majority of cases, and when we consider that nearly all the patients presenting themselves are chronic invalids, the six weeks or so necessarily spent in hospitals when the fistula is opened is by no means too long a period in which to obtain relief from a condition which often has existed for nearly as many years.

What Can Be Done to Check the Progress of the Age Degenerations?—Bradford C. Loveland calls attention to the degeneration of arteries and arterioles or capillaries incident to advancing years and imperfect elimination.

When we consider that apoplexy, paralysis, most senile conditions affecting the brain and nervous system, Bright's disease and diabetes, senile gangrene, angina pectoris, and many other conditions are dependent upon this as a fundamental cause, a considerable majority of all deaths occurring after middle life may be charged to the account of degenerated arteries. He concludes that the etiology of arteriosclerosis may be narrowed down to one of poisoning and the elimination of toxic material; consequently it is logical to suppose that after the removal of the cause the progress of the disease will be arrested. He relates three cases in which there was not only a limiting of the process, but relief from certain symptoms which had been present for some time, and in a certain degree an improved circulation in the parts supplied by the diseased blood-vessels. This improved circulation might result in absorption of the thickenings which had narrowed the lumen of the vessels or a bettered general circulation. It seems natural to suppose that a mode of living which will result in so much improvement should, if persistently adhered to, prevent death from this cause, and that an improvement so lasting would involve actual improvement in the tissues.

American Medicine, September 10, 1904.

The Early Recognition and Treatment of Intestinal Obstruction.—Andrew Stewart Lobinger sums up as follows the symptoms in intestinal obstruction, which appear early and which are our principal dependence in diagnosis: Obstipation, vomiting persisting more than fifty hours, pain, more or less severe and constant; shock or collapse, meteorism, of localized character; normal or subnormal temperature; a rapid small pulse and a leucocytosis between 15,000 and 20,000, with a strong reaction of indicanuria if taken before the third day, and the ileum is involved. Besides these symptoms, it is most valuable in relation to diagnosis, to give the closest scrutiny to the past history of the patient. Oftentimes, such an analysis will yield an immediate and correct diagnosis. Constricting bands or adhesions may be present as the result of various conditions. Gibson found in 1,000 cases in which operation was done for acute intestinal obstruction, that bands were the cause of the obstruction in 186 cases. The hernial openings must be carefully examined. Late operative interference is the principal cause of mortality. A surgeon should be consulted at the very beginning of the trouble. When vomiting is an early and depressing symptom, gastric lavage will do much to rest and quiet the patient. But this tranquility is sometimes deceptive, and vigilance should not be relaxed. Only a very thorough evacuation of the bowels, with general subsidence of characteristic symptoms, should be reassuring. Simple release of the constricting band will often suffice if the patient is seen before serious necrobiotic change occurs in the gut However, if destructive changes have taken place, it will be a question of judgment whether immediate exsection of the gangrenous segment and anastomosis shall be accomplished, or simple suture to the abdominal wall and enterotomy shall be done. If the patient is too weak for prolonged anæsthesia, then a primary enterotomy, establishing an artificial exit for the gas and intestinal contents, will prove safer. An anastomosis can be made later. Every effort should be made to support the patient, and to prevent further shock. The greatest care should be observed in all the details of technique in order to avoid future complications.

Pathogenesis of Chronic Gastric Ulcer.—W. G. MacCallum states that a satisfactory explanation of the chronic progressive ulcer has not yet been attained in spite of the numerous researches that have been made by various investigators. As early as 1855, Virchow stated that he believed that the condition is essentially due to the disturbances in the circulation of the stomach—embolism, thrombosis, arteriosclerosis, aneurysm formation. In other words, any change which might result in the cutting off of the blood supply from a part of the stomach could cause the death of that part and its subsequent digestion. Müller produced ulcers by causing a chronic venous congestion by tying the portal vein. Axel Key believed that spasm of the muscles produced a passive venous congestion and favored ulcer formation. Talma stimulated the vagi, thus producing hemorrhagic erosions. He thought that this was due to the infarction and digestion of parts of the stomach rendered anæmic by the violent muscular contraction set up by this means. Many authorities have explained the genesis of the ulcer on the grounds that mechanical, chemical, or physical influences have destroyed the tissue. Rasmussen holds that the chronic ulcers may often be traced to the pressure on the stomach from tight lacing. Leube and Decker have noted cases in which burning the mucosa with hot food will cause ulceration. It is difficult to explain the persistence of the round ulcer, especially on account of the remarkable power of healing which characterizes the walls of the stomach. Writers are unanimous, however, in speaking of it as a peptic ulcer. The writer concludes by saying that gastric ulcers may be produced by anything which causes necrosis of the mucosa of the stomach, and thus subjects it to the digestive action of the gastric juice. While certain cases may be explained in their origin by one or other of the causes given, there are others whose inception is obscure. The persistence of some of these ulcers offers the greatest difficulty of explanation, and none of the theories is satisfactory. Perhaps the majority of gastric ulcers do heal, however, and are recognizable later only by the scars they leave, so that possibly Talma is right in saying that all ulcers tend to heal, but that frequently they last a long time, because new ulceration occurs in the same spot.

Deutsche medizinische Wochenschrift, August 25, 1904.

Removal of Urates and the Joint Capsule from the Gouty Toe.—Riedel believes that very good results attend this method of treatment, although he has had the opportunity to try it in but two cases, for the disease rarely ever comes within the scope of surgical treatment. In the first case, an operation was undertaken for what was believed to be a suppurative arthritis of the great toe. The incision revealed a joint filled up with urates, which were cleaned out and the thickened capsule removed. The patient made an uninterrupted recovery and remained free from joint symptoms until his death twelve years later from some other disease. The second patient was a woman of seventy, who was similarly operated upon and remained well until her death six years later from aortic stenosis. The writer admits that this procedure is only applicable to cases in which the gouty process is localized; when it is general the usual therapy must be employed. In doing the operation it is well to leave the wound wide open, and simply pack it.

Acute Pancreatitis with Recovery after Laparotomy.—Wiesinger reports two cases of this disease with disseminated fat necrosis, which have remained cured after operation for a period of over a year. In both of these cases the prodromal symptoms consisted of digestive disturbances, which were followed by severe epigastric pain, repeated vomiting, lack of stools and flatus, alternating with profuse diarrhœa. The diagnosis was not made until the laparotomy disclosed areas of fat necrosis scattered through the abdominal cavity. This affords a conclusive symptom, and when found, the blood stained serum should be evacuated, the bursa omentalis drained, but the abdominal contents should be disturbed as little as possible. In both of these cases there was no sloughing of the pancreas. The author thinks that operation is always indicated and should, if possible, be done without a general anæsthetic. In one of the writer's cases, a second laparotomy undertaken for another purpose, a year later, showed that the necrotic areas had entirely healed.

The Spontaneous Cure of Cancer.—R. Borrman discusses the statement made by a number of observers that the giant cells in carcinoma of the skin must be looked upon as part of a curative process. He himself has examined 265 cases, which he intends to report on shortly in another periodical. His observation agrees with those of the other investigators, but he considers that they have placed a wrong interpretation on their findings. He thinks that the giant cells may possibly be formed around foreign bodies, but that they do not surround living cells, particularly proliferating tumor cells. A spontaneous cure could be thought of only if the latter condition took place and the tumor cells were destroyed. This, however, does not occur. In rodent ulcers, which may exist in a quiescent state for prolonged periods, and in which the condition noted might be expected, nothing of the kind was found. The writer claims, moreover, that the giant cells are met with in greater number in the rapidly growing, than in the slowly developing types of carcinoma. There can be no question of a phagocytic action similar to that associated with the disposition of dead material in other parts of the organism, but in which the giant cells play the active rôle.

Berliner klinische Wochenschrift, August 22, 1904.

Follicles and Erythema Induratum.—A. Alexander presents a summary of the clinical work which has been done on the subject of tuberculous diseases of the skin by the dermatologist. In addition to the well-known forms there are two other types which have been designated as a papulonecrotic tuberculide (follicles) and the erythema induratum of Bazin. These lessons have been ascribed to the agency of the toxins and to the tubercle bacillus, and it is the writer's opinion that they must be considered in the light of present knowledge, as the halting places of weakened tubercle bacilli. Depending on the manner in which they settle, either the one or other form of the disease is created. Practically the presence

of this skin lesion means that somewhere in the body there is a tuberculous focus and a general infection of the organism has already taken place or may result at any moment. The two forms mentioned are to be considered as a projection of a visceral tuberculosis on the skin, and therefore deserving of attention.

The Establishment by Surgical Means of Anastomotic Channels for the Blood of the Portal Vein.—S. Talma discusses certain points in reference to the operation with which his name is largely associated. These he puts in the form of the following questions: (1) Can the deviation of the blood from the portal vein favorably influence the hepatic cirrhosis itself? In connection with this it also remains to be seen whether the icterus accompanying this condition may also be thus successfully treated. (2) Can an omentopexy reduce the danger of hemorrhage from the overdistended veins of the abdominal viscera? (3) Does the opening of new anastomotic channels in portal thrombosis obviate the severe circulatory disturbances? Ad (1), he believes that experience has not shown that the collateral circulation has had any influence on the cirrhosis and at the present time the outlook cannot be considered favorable. The hepatic process may be favorably influenced, but it does not continue to complete cure. Ad (2), he states that he still adheres to his previous claims, that hæmatemesis with hepatic cirrhosis indicates fixation of the omentum and that œsophageal varices may be avoided by the performance of a timely omentopexy. The question still remains as to whether this procedure will also cure the varices already developed in the abdominal viscera, especially the gullet. Three cases which the author observed remained well after operation and the bleeding ceased, but no anatomical examinations could be made. Ad (3), he reports a case of portal thrombosis upon which he operated, but without favorable results, so that he is inclined to abandon the method were it not for the more favorable report of a case by Umber, in which at autopsy numerous adhesions (natural) were discovered which seemed to compensate for the presence of a plugged portal vein which had evidently been in this condition for many years.

Munchener medizinische Wochenschrift, August, 23, 1904.

Experiments on the Motor Function of the Vagus.—H. Starck discusses the influence of the vagus nerve on the œsophagus and the cardiac end of the stomach and also the results of his attempts to produce dilatation of the gullet by experimental means. The latter was carried out in dogs in which unilateral and bilateral resections of the vagi were done. It was found that the inhibitory impulses going through the vagus to the cardia were not of any great moment. No spasm results, and the passage of fluids and of the œsophagoscope is not interfered with. It is evident therefore that this condition cannot act as a permanent obstruction to the passage of food and is not a factor in the formation of the chronic œsophageal dilatation. As for the effect which the vagus manifests over the musculature of the stomach, it was seen that vagotomy above the hilus of the lung alone was followed by any effect. A paralysis resulted which interfered with peristalsis, so that solid food became fixed in the gullet, although fluids found their way into the stomach. Permanent dilatation could not be observed because it was impossible to keep the animals alive. It does not seem reasonable to assume that degeneration of the vagus is the cause of œsophageal dilatation unless in exceptional instances. A vagotomy below the hilus shows that the important motor fibres evidently enter the œsophagus above the level of the hilus, because resection at this point shows no permanent influence on the motor functions of the œsophagus.

Absorption of Pure Albumin in the Intestinal Canal of New-born Infants and Animals.—Ganghofer and Langer have been led to their investigations by the claims made by Romer that pure albuminoid substances pass through the intestinal walls of the new born without undergoing any change and have the same effect on the organism as if they had been injected directly into the circulation. In adult animals conversion into peptones is necessary before absorption can take place. As this was proved for diphtheria antitoxin and like substances, the writers endeavored to determine whether a similar process existed with reference to nutrient materials in the intestine of the newly born, and if this were the case, to what age this phenomenon persisted. The experiments consisted of giving the albuminoid materials by mouth to young animals and then testing their blood serum for specific precipitation with homologous immune serum. The results may be summarized as follows: The property of absorbing the albuminoids unchanged was found, in animals examined, to persist until the end of the first week after birth, and then it could no longer be determined. Similar conditions were also found in the human infant, but here the phenomenon seemed to be present for a longer time, but of which the extent has not yet been fully determined. The intestinal canal of older animals does not permit the passage of albuminoids taken by mouth, unchanged, under normal conditions. But if the quantity administered is unduly large, or there exists an anatomical or functional derangement of the epithelium of the intestinal tract, the passage of unchanged albuminoids directly into the circulation is possible. The absorption of the unchanged albuminoids was shown in one instance to have brought about the formation of antibodies. It was found, however, that this usually resulted in the animal becoming ill and losing weight, and the process must therefore be considered harmful to the organization.

French and Italian Journals.

Contribution to the Theory of Immunity.—Capellani Salvatore has studied experimentally in animals the question as to what is the cause of the immunity conferred by the use of antitoxins, whether it is due to a passive resistance developed by the system or whether there is formed in the blood a specific resisting substance acting as an antidote. While making preparations of diphtheria bacilli from an animal previously immunized with Behring's serum, he noticed that the bacilli were all very much elongated and swollen, with an approach to segmentation, and a classic key-like termination. He repeated experiments on this subject, and became convinced that this change in shape was due to the immunization, to the presence in the blood of some substance which acted directly on the bacilli. He now immunized guinea-pigs, and introduced into the peritoneal cavity sacs made of collodion, filled with diphtheritic cultures; he allowed these to remain a few days, then removed and examined them. The bacilli had become clavate in shape. The changes in the bacilli were believed to be due to the action of some specific antitoxic substance in the fluids circulating in the animals experimented on. The author concludes that we cannot speak of a passive immunity in the animal immunized, but must admit the production of a special secretion, inimical to the diphtheria bacilli.—*La Riforma Medica*, August 3, 1904.

A Case of Broncho-œsophageal Fistula with Mediastinal Adenopathy Consecutive to Tuberculous Pericarditis.—Péhu reports the case of a woman aged sixty-six years, with negative antecedents. She had, however, suffered with bronchitis for a year. There were no signs of tuberculosis. For the last month the patient had suddenly begun to lose her strength and had grown thin. About the same time she noticed that food was swallowed with difficulty. Dyspnœa also had developed. The patient had a cachectic aspect. A large subclavicular ganglion was detected. There was no alteration of voice, and the pupils were normal. There were signs of a pleural effusion. The pulse was 120. Albuminuria was present. The clinical diagnosis was that of cancerous stenosis of the middle part of the œsophagus. The patient died the day after entering the hospital. Autopsy revealed the true state of affairs. Caseous, mediastinal adenopathy does not ordinarily entail fistulæ between the œsophagus and the bronchi. It has been observed in 107 cases that 68 perforations were due to a neoplasm of the alimentary canal, while 17 were due to tuberculosis of ganglia. In this series of cases, the communication was more often between the left bronchus and the œsophagus, while in the author's observation it was associated with the right bronchus.—*Lyon Médical*, August 14, 1904.

Total Visceral Transposition.—L. Baldenweck reports that different authorities hold contrary views concerning the frequency of this anomaly. He himself believes it to be comparatively rare. In all of these cases the organs seem to possess their habitual comparative relations. In other words, the arrangement is such that were they viewed in a mirror, the image would be that of a normal individual. There is nothing to hinder longevity in these cases, one of whom is known to have lived to the age of eighty years. The absolute position of the human organs is not important. The writer mentions twelve cases, stating the various diseases from which they suffered. But the number of cases is too small for a deduction of any conclusions. The pulmonary troubles exceed the others in number, however. Certain malformations have been detected in some of these cases, such as deformity of the thorax, and a very small pancreas. As to the diagnosis, the important points are the situation of the heart, determined by palpation, percussion and auscultation, the position of aortic sounds, the position of the liver and stomach by means of percussion. Insufflation can also be used in relation to the stomach. Radioscopic examination is also a very important method of examination. The theory for this anomaly that is most generally accepted, is that in the normal condition, the embryo is placed at the left of the vitellus; if for some unknown cause, it is placed at the right, there will be an inversion of the viscera.—*La Tribune Médicale*, August 6, 1904.

Book Reviews.

A Textbook o Human Physiology. By Albert P. Brubaker, A.M., M.D., Professor of Physiology and Hygiene in the Jefferson Medical College; Professor of Physiology in the Pennsylvania College of Dental Surgery; Lecturer on Physiology and Hygiene in the Drexel Institute of Art, Science and Industry. With Colored Plates and 354 Illustrations. Philadelphia: P. Blakiston's Son & Co., 1904.

The special object in view in the preparation of the volume before us was the condensation and selection of the general subjects in physiology which would have a bearing on modern medicine. The estimation of the proportionate values of the different subjects has been most ably performed, as one would expect from an author who has had twenty years of practical teaching at different colleges. The general text avoids very wisely the description of the different physiological apparatus, only including those which would be of use to the clinician and some of the very important ones used in the investigations of purely experimental work. The work follows the general order of modern works on physiology, is richly illustrated with plate and diagrams, has a most lucid text, and in short fulfils its intended purpose most satisfactorily.

The Treatment of Some Acute Visceral Inflammations, and Other Papers. By David B. Lees, M.A., M.D. Contab., F.R.C.P. (London). Formerly Scholar of Trinity College, Cambridge; Senior Physician to the Hospital for Sick Children, Great Ormond Street; Physician to St. Mary's Hospital; Late Examiner in Medicine for the University of Cambridge, the University of Durham, the Victoria University, and the Conjoint Board for England. Philadelphia: P. Blakiston's Son & Co., 1904.

The author, who has had a large experience as a clinician both in hospital and private practice, here gives his views, part of which were expressed before the Harveian Society of London in 1903. They consist of a series of short articles which advocate certain methods, among which might be mentioned the importance of mapping out the size of the left ventricle and right auricle in cardiac and pulmonary disease, the great good accruing from venesection and leeching when the right heart is distended, the advocacy of the use of ice-bags in pneumonia, pericarditis, pleurisy, and sometimes in appendix and kidney diseases, and the value of larger doses of the salicylates combined with an alkali. Besides these lectures he reprints various articles which in part deal with the same subjects and in part with allied subjects. The book as a whole makes instructive reading, and deals with the details in therapeutic procedures in a way many of the modern works would do well to imitate.

Traité de Médecine. Deuxième Edition. Publiée sous la Direction de MM. Bouchard, Professeur à la Faculté de Médecine de Paris, Membre de l'Institute, et Brissaud, Professeur à la Faculté de Paris, Médecin de l'Hôpital Saint-Antoine. Tome IX. Paris: Masson et Cie. 1904.

After a delay of nearly two years the ninth volume of this greatest of French systems of medicine is published, and the speedy appearance of the tenth volume, completing the series, is promised. These concluding volumes are on diseases of the nervous system. The ninth volume contains the following articles: "Diseases of the Cerebral Hemispheres," by E. Brissaud and A. Louques; "Diseases of the Cerebellum," by L. Tollemer; "Diseases of the Cerebral Peduncles, the Corpore Quadrigemina, the Pons, and the Medulla," by Georges Guillain; "Secondary Degenerations," by P. Marie and Georges Guillain; "Intrinsic Diseases of the Spinal Cord," by P. Marie, André Lévi, O. Crouzon, and G. Guinon; "Extrinsic Diseases of the Spinal Cord," by G. Guinon; "Diseases of the Meninges," by G. Guinon; and "Syphilis of the Nervous Centers," by H. Lamy. There are some 320 excellent illustrations distributed through the 1100 pages of text. This volume, with the next of the series when published, will without question constitute not only the latest, but one of the best treatises of the nervous system in any language.

A Textbook of Pathology. By Joseph McFarland, M.D., Professor of Pathology and Bacteriology in the Medico-Chirurgical College of Philadelphia; Pathologist to the Medico-Chirurgical Hospital, Philadelphia. Philadelphia, New York, London: W. B. Saunders & Co., 1904.

This work, the author tells us, is intended especially for the use of students who have to acquire the first principles of the science and have no need to concern themselves with the discussion of pure theories and disputed questions. The latter have, therefore, been omitted for the most part or touched upon as lightly as possible. It is well for the size of the volume that they have been, for as it is the work fills over 800 closely printed pages. The author makes the usual division into general and special pathology, devoting about half the book to each division. The long teaching experience which Dr. McFarland has had has well qualified him for the task of writing a textbook on this fascinating subject, and he has done it well. To students, especially those who have the privilege of receiving instruction from the author in person, this book will be invaluable, and practitioners as well can find here all that any but a specialist would need.

Le Liquide Céphalo-Rachidien. Par le Dr. Milian, Ancien Interne des hôpitaux de Paris, Ancien Chef de Clinique à la Faculté de Paris. Paris: G. Steinheil, 1904.

This work is a résumé of our present knowledge regarding the cerebrospinal fluid. It also contains an extensive bibliography and a report of original research. The subject is divided into four parts: (1) The origin, circulation, physical and chemical characters, and the physiology of the cerebrospinal fluid. (2) Its pathological conditions and the special technique in its study; its semeiological value in meningeal hemorrhage and fracture of the skull. (3) Its pathological cytology in acute and chronic processes. (4) Lumbar puncture and intraspinal cocainization. The practical clinical part of the book relating to the technique of lumbar puncture and spinal anæsthesia is clearly and concisely written and well illustrated.

Dermatologische Vorträge für Praktiker. von Dr. S. Jessner, Königsberg. Zweite Auflage. Würzburg: A. Stuber's Verlag (C. Kabitzsch), 1904.

There are three of these little fasciculi on practical skin subjects—one on psoriasis, one on the internal treatment of cutaneous affections, and the third on the cutaneous diseases of children. They are all well prepared and of decided interest.

A Textbook of Alkaloidal Therapeutics. Being a Condensed Résumé of All Available Literature on the Subject of the Active Principles, Added to the Personal Experience of the Authors. By W. F. Waugh, M.D., and W. C. Abbott, M.D., with the collaboration of E. M. Epstein, M.D. Chicago: The Clinic Publishing Co., 1904.

The authors of this book are well known throughout the country as enthusiastic advocates of the therapeutic principle of "the smallest possible quantity of the best obtainable means to produce a desired therapeutic result," and their enthusiasm appears on every page of their work. There is no therapeutic nihilism here—pessimism may do for the closet therapist, but in the bright vocabulary of the alkalometrist there is no such word as fail. One who can make allowance for this will have his ideas broadened and some prejudices removed by a careful study of it. To those who already believe in the therapeutic superiority of active principles over the crude drugs, and to those who prefer the latter, believing that the so-called active principle is only one of many substances of therapeutic value in the plant, this book will be equally useful—to the former as a guide, to the latter as opening their eyes to the fact that, whatever may be the value of the crude drug, the alkaloid or glucocide has also its place, and a very important place, in therapeutics. The book is interleaved with blank pages for the convenience of the reader in recording his own experiences. The authors have written a work which cannot fail to be useful to a large class of physicians.

Chirurgie Nerveuse d'Urgence. Par le Dr. A. Chipault, Ancien Chef de Consultation Chirurgicale à la Salpêtrière. Paris: J. B. Ballière et Fils, 1904.

This is one of a series of books published under the title of "Les Actualités Médicales." The author describes the various traumatic and infectious processes involving the nervous system which require immediate or early surgical intervention. The technique for such operations is set forth in detail.

The Optical Dictionary. An Optical and Ophthalmological Glossary of English Terms, Symbols, and Abbreviations, together with the English Equivalents of some French and German Terms, Relating to Physical, Physiological, and Pathological Optics, Optical, and Other Instruments of Precision, and Terms Descriptive of Color and Photochemistry; to which are added a Number of General and Mathematical Expressions. Edited by Charles Hyatt-Woolf, F.R.P.S., Editor of the Optician and Photographic Trades Review, etc. Philadelphia: P. Blakiston's Son & Co., 1904.

The scope of this work is sufficiently set forth in the descriptive title, and it remains for the reviewer only to say that in the main the editor's work appears to have been well done. The definitions are concise, for the most part clear, and, as far as we have been able to discover, correct. To opticians, and even to medical men without an ophthalmological training, the book will undoubtedly be of great service.

Society Reports.

CANADIAN MEDICAL ASSOCIATION.

Thirty-seventh Annual Meeting, Held in Vancouver, B. C., August 22, 23, 24, and 25, 1904.

(Special Report to the MEDICAL RECORD)

FIRST DAY—TUESDAY, AUGUST 22.

THE meeting was called to order at 10 A.M. by the president, Dr. Simon J. Tunstall. The secretary read the minutes of the last meeting and presented his annual report. The report called attention to the rapidly increasing membership of the association and urged a better and more complete organization of the society upon the lines of the British Medical and American Medical Associations. Dr. Small gave notice of motion to amend the by-laws.

Addresses of Welcome.—Dr. BRYDONE-JACK, secretary of the local reception committee, delivered an address of welcome on behalf of the resident physicians. He outlined the many entertainments that were to be given and other arrangements for the meeting.

Dr. MCGUIGAN, the mayor of Vancouver, welcomed the visitors on behalf of the city. His address was replete with western hospitality. The importance of the meetings of the Canadian and also (next year) of the American Medical Association upon the western coast was dwelt upon, and he hoped all would carry away pleasant recollections of their visit. He explained that in British Columbia a high standard of medical ethics was maintained, as shown by the absence of all forms of advertising by the members of the profession, and the absence of any illegal practitioners.

Dr. DAVIS of Victoria spoke on behalf of the College of Physicians and Surgeons of British Columbia.

Address in Medicine.—R. E. MCKECHNIE of Victoria, B. C., delivered the annual address in medicine. He sketched the career and manners and procedures of the "medicine man" in the treatment of disease among the native Indians, as it had come under his notice. He instanced a case of tuberculous pleurisy in which the Indian medicine man and his assistants were endeavoring to drive out the evil spirit which was looked upon as the cause of the trouble. The recent advances in medicine were also sketched, particularly the advances in the treatment and cure of consumption.

Prevention of Tuberculosis.—The following resolution was moved by Dr. R. E. McKechnie of Vancouver, and seconded by Dr. R. E. Walker of New Westminister:

"*Whereas*, Tuberculosis has been positively proved to be an infectious disease;

"*Whereas*, The patient is the focus of infection and is capable of infecting, and does infect dwellings, clothing, and private and public places generally. Statistics already available prove that compulsory notification with educational oversight of the patient and those under exposure to the contagion, together with disinfection of infected materials and places, has resulted in a diminution of the number of cases;

"*Whereas*, Such action in the Dominion of Canada lies with the various provincial governments;

"*Therefore be it resolved* that the various provincial authorities be and are hereby urged to take at once the necessary steps to bring these suggestions into effect, and that the secretary be requested to forward copies of this resolution to the secretaries of the various provincial boards of health."

Patent Medicines.—Dr. C. J. FAGAN, Victoria, B. C., made a strong plea for the profession to take active steps to combat this growing evil. He dwelt upon the extensive employment of patent medicines and the luring advertisements met with in publications. The various methods to be followed were outlined, such as applying to the Postmaster-General to prevent the transmission through the mails of such literature, or calling the attention of the Minister of Inland Revenue to the large percentage of alcohol contained in many of these so-called remedies. A lengthy discussion followed, and Dr. Fagan was requested to form a committee of such as he wished to associate with him and formulate a method of action in the matter

Neuroses as Seen in Orthopedic Surgery.—Dr. B. E. MACKENZIE of Toronto read this paper, which consisted of a series of observations and reports of cases of deformity of purely neurotic origin. His treatment was massage and gymnasium exercises with fresh air and good food.

Case Reports.—Dr. ROBERT H. CRAIG of Montreal reported the following: Papilloma of the larynx, child aged seven, high tracheotomy, thyrotomy. Empyema of the right sphenoidal cavity, associated with occlusion of the right posterior nares. Empyema of the right frontal and sphenoidal cavities.

SECOND DAY—WEDNESDAY, AUGUST 23.

Address in Surgery.—WM. MAYO-ROBSON of England delivered this address. He selected as his subject the diseases of the pancreas in so far as they were related to the production of disturbances in the gall-bladder. His preliminary remarks were upon the anatomy and physiology of the organ and the changes produced by pancreatitis. The direct extension to the gall-bladder and the ill effects produced by the enlarged pancreas in distorting the biliary passages were impressed upon the members. He made a strong plea for early operation in all cases and advocated large and free incisions. He also greatly favored the use of chloride of calcium to prevent a too free hemorrhage.

Hernia of the Bladder Complicating Inguinal Hernia.—Dr. F. J. SHEPHERD of Montreal read this paper, which was a report of three cases of hernia in which the bladder formed part of the hernial protrusion. He urged the importance of emptying the bladder and of a careful examination for this complication before all hernial operations.

Movable Kidney.—Dr. KENNETH MACKENZIE of Portland gave a statistical record of his cases and the results of operations. He also discussed the important question as to the effects of the operation in relieving neurasthenic symptoms. The result of his experience was that each case required to be considered by itself, and that when the proper results were to be obtained the patient would require to be carefully treated for the weakness and prostration for some time after recovery from the operation.

Hypertrophy of the Breasts.—Dr. S. R. JENKINS of Charlottetown, P.E.I., reported this case, which was one in which an enlargement of both mammæ began in a young girl and slowly increased until they acquired an enormous size. Partial excision was performed, but the growth recurred.

Therapeutic Hints from Bacteriology.—Dr. D. CRUIKSHANK of Windsor, Ont., reviewed the serum remedies, their evolution, and what was to be expected of them in the future. Their superiority to drug medication was emphasized.

President's Address.—Dr. SIMON J. TUNSTALL of Vancouver, in this address, thanked the members for the honor they conferred on him, and for coming so far to attend the meetings. The ground on which the city was built, less than two decades ago, was virgin forest, and is now a city of forty thousand inhabitants. He sketched the history of medicine in the province, giving much attention to the "medicine men" of the nations, liking their treatment to that of the mesmerist and suggestive therapeutist of the present day. Dr. Tunstall then dwelt at length on four medico-political points of Canadian interest: The Canadian Medical Protective Association; A Dominion Health Department; Interprovincial Regis-

tration, and Government Care and Treatment of Inebriates.

Surgical Treatment of Complete Descent of the Uterus.—Dr. E. C. Dudley of Chicago read a paper with this title. Complete descent of the uterus, he said, descent to the third degree, which might be defined as that deviation in which a part or whole of the uterus was outside the vulva, was always associated with extensive injury to the pelvic fascia, the pelvic connective tissue, the muscles of the vaginal outlet, the perineum, and the vaginal walls —in fact, these injuries of the pelvic floor constituted the essential lesion, the mal-location of the uterus being an incidental factor.

In operating to relieve the displacement in addition to restoring the lacerated structures, it was important to return and hold the uterus in its normal angle in relation to the vaginal canal. The ordinary operation sought to suspend the uterus in the pelvis without regard to the relative position of the uterus and vagina. Generally speaking, the indications for treatment were somewhat as follows: (1) Extreme cystocele not associated with the most extreme procidentia should be treated by anterior colporrhaphy and perineorrhaphy. (2) Cystocele, associated with complete procidentia, properly might be treated by hysterectomy, anterior colporrhaphy and perineorrhaphy. (3) Conditions intermediate between the two conditions indicated above and cases in very feeble or very aged women would call for special judgment, whether hysterectomy be omitted or performed.

A Latern-slide Clinic.—Dr. Dudley then gave a unique exhibition in which he showed many views of operative procedures and pathological conditions after the same manner as in a bedside clinic. It proved most interesting to all present.

Third Day—Thursday, August 24.

Tuberculous Peritonitis.—Dr. C. H. Mayo of Rochester, Minn., read this paper. He looked upon this as a comparatively rare disease. Operation was frequently performed for peritoneal tuberculosis with success, but its mode of cure was unexplained. He advised careful search for the cause of the trouble before operations were begun. The disease was more frequent in women than in men, in the ratio of about five to one. A simple incision in some cases was all that was necessary, in others the conditions were such as to require a separation of adhesions and irrigation. Repeated operation was often necessary.

Meckel's Diverticulum.—Dr. H. Howitt of Guelph read a paper with this title, which was a review of our knowledge of this abnormality, with report of four cases. Dr. Howitt advocated resection of the intestine, as in his experience simply removing the diverticulum has resulted in a stump which favored intussusception of the bowel, an occurrence he had met with as a result in two cases.

Operative Treatment of Spina Bifida.—Dr. E. R. Secord of Brantford read a very exhaustive paper on the subject. The following conclusions were presented: (1) There are no absolute contraindications to the operative treatment. The more severe the case the more marked is the futility of other than operative treatment. (2) As to method: In meningocele, opening of the sac after dissecting up the skin, suture of neck and removal of redundant tissue. In myelomeningocele and syringomeningocele, the same method combined with loosening of the nerve cords and return of the same to the canal. (3) As to prognosis, meningocele, with more extended experience should yield uniformly favorable results.

Fourth Day—Friday, August 25.

The session, held in the morning of this day, was purely a business meeting. It was voted to meet in 1905 at Halifax, N. S.

Officers.—The election of officers resulted in the choice of the following: *President*, Dr. John Stewart, Halifax; *Vice-Presidents*, Drs. McLaren Montague, Bridge, P. E. I.; J. B. Black, Windsor, N. S.; A. B. Atherton, Frederickton, N. B.; Jos. E. Dube, Montreal, Que.; H. Meek, London, Ont.; W. E. England, Winnipeg, Man.; H. C. Wilson, Edmonton, N. W. T.; R. E. Walker, New Westminister, B. C.; *Local Secretaries*, Drs. H. D. Johnson, Charlottetown, P. E. I.; G. C. Jones, Halifax, N. S.; T. D. Walker, St. Johns, N. B.; J. D. Cameron, Montreal, Que.; D. Stewart, Palmerston, Ont.; Popham, Winnipeg, Man.; Hewettson, Pincher Creek, N. W. T.; A. S. Monro, Vancouver; *General Secretary*, Dr. George Elliott, Toronto; *Treasurer*, Dr. H. B Small, Ottawa; *Executive Council*, Drs. G. M. Campbell, Halifax; J. Ross, Halifax; C. D. Murray, Halifax.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Twenty-sixth Annual Meeting, Held at Atlantic City, June 2, 3, and 4, 1904.

President's Address.—Dr. J. H. Hartman of Baltimore, in his presidential address, called attention to the fact that the ranks of the Association had not been broken during the past year. It was suggested that the Association send a message of good wishes to Señor Manuel Garcia, an Honorary Fellow, the discoverer of the laryngoscope some fifty years ago, who, on March 17 last, passed his ninety-ninth birthday. Mention was made of the various new methods for treating diseases of the nose and throat, especial attention being directed to the examination of the œsophagus and bronchi by Killian's method, and to Gersuny's method for the subcutaneous injection of paraffine for the correction of nasal deformities. Hay fever and its treatment was touched upon. The question of enlarging the membership of the Association was endorsed by the President. He called attention to the fact that many of the members were now reaching the stage when their period of active usefulness would not be as great as in the past, and he believed the introduction of younger men to the rolls would be a great advantage to the Association in general.

Secreting Mechanism of the Nose.—Dr. J. L. Goodale of Boston read a paper entitled "A Contribution to the Study of the Secreting Mechanism of the Nose." The author, after a review of the literature of the subject, called attention to the fact that the mucous membrane of the nose contained two arrangements for the production of nasal fluid, viz., the glands and the intercellular spaces of the epithelium and the underlying basement membrane. Up to the present time it has not been determined in the membrane of the nose whether serous glands occurred in addition to the mucous glands or not, and, therefore, the writer determined to investigate the subject by the newer methods of Golgi and by Retzius, which have proved serviceable in the demonstration of serous glands in the larynx and trachea. It was found that in normal cases the mucous membrane of the respiratory portions of the nose contained both mucous and serous glands in association. Attention was next called to the alterations produced in the glands of the nasal mucous membrane and in the canals of the basement membrane, and different pathological conditions, such as chronic inflammations characterized by increase of mucous secretion, chronic atrophic inflammations, and vasomotor rhinitis. It was found that chronic inflammations characterized by increase of mucous secretion showed a heightened activity in the mucous glands irrespective of the secondary changes produced in the other constituents of the tissues. Atrophic inflammations showing tenacious fetid mucous, exhibited a complete disappearance of the canals of the basement membrane, while the mucous and serious glands showed a diminished but still a distinct degree of activity. In vasomotor rhinitis there

is a striking increase in the looseness of structure of the epithelium and in the number and size of the basement canals, an alteration which is distinctly out of proportion to the moderate increases in the mucous and serous glands. Physical examinations in connection with these histological findings render it probable that the greater portion of the vapor impaired and the inspired air of the nasal membrane is derived from the fluid which reaches the surface through the basement canals and interspaces of the epithelium.

Dr. H. L. Swain of New Haven said that he had found, in decalcifying the bone of the middle turbinate, that there were a great many mucous glands situated in the region of the middle turbinate, sometimes a perfect mass of glands being found, and he believes this accounts for the great amount of mucous found in this region. With regard to the question of the amount of fluid existing in the nose at any one time, Dr. Swain stated that in cold weather there is an accumulation in the nose because of the outside air, and laid stress upon the fact that a great deal of the moisture found in the nose in cold weather came from the lacrymal glands.

Dr. James E. Newcomb of New York agreed with Dr. Swain that there could not be a too careful study of this subject. He referred to the use of mucin in atrophic rhinitis, and stated that he had employed this remedy for over a year with satisfactory results.

Dr. Goodale, in closing the discussion, agreed with Dr. Swain that there was a large number of glands found in the region of the middle turbinate. His special object was to call attention to the new facts in the histology, which he did not find in the literature on laryngology.

Report of a Case of Nasal Hydrorrhœa.—Dr. J. Edwin Rhodes of Chicago reported the case. He stated there had been little added to the literature of this subject since the presentation of Dr. Bosworth's contribution in 1889, when abstracts of the sixteen cases then on record were given. There have been presented since that time, however, a number of theories as to the etiology of this condition. In regard to the differentiation between cerebrospinal rhinorrhœa and nasal rhinorrhœa it was stated that the laboratory test of St. Clair Thomson was sufficient to determine the difference. The cerebrospinal fluid was supposed to come from the subarachnoid space and to find its exit through the nasal cavities. Possibly it found its way by filtering down through perineural sheaths or through traumatic openings in the skull, the results of injuries, etc. It was said that it differed from true nasal hydrorrhœa in some of the symptoms, and the two conditions should no longer be classified together, but considered as quite distinct in character. Nasal hydrorrhœa was defined as a copious flow of watery fluid from the nasal mucous membrane, either continuous or appearing at certain times during the day, or at irregular intervals, and sometimes persisting for long periods of time. It might come from both nares, but was more often one-sided. The two theories which had received the greatest recognition were: first, that it was anœrosis of the trifacial nerve in the nasal mucoso; and second, that it was one of the symptoms of a general neurasthenic condition. The author believed the neurasthenic character of the disease to be fairly well established and thought that probably the exosmosis of the fluid was due to the irritations of the terminal filiments in the nasal mucosa of the trifacial nerve, the exciting cause, although not well established, being probably due to some obscure atmospheric condition. The main symptom of the condition was the discharge of a clear, limpid fluid from the nose: the other symptoms were headache, insomnia, cough, sneezing, nervous phenomena, etc.

Dr. Rhodes then related the case of a woman aged forty-four years, who complained of a constant dripping of fluid from the right naris. She was given a pill of zinc phosphide, nux vomica, and quinine with benefit to her nervous condition, and bromide was given to quiet her at night. Various remedies were tried without the slightest benefit until a solution of argentum nitras in small quantities, 60 grains to the ounce, was used over a portion of the nasal cavity only. This caused some pain and a slight headache, but was immediately followed by the cessation of the dripping for a few minutes. Later, the nasal cavity was swabbed first with a 1-1000 suprarenaline solution, then the 60-grain solution of nitrate of silver was applied to the entire accessible parts of the nasal cavity. This treatment was followed by very severe headache, but five days later the headache ceased and the discharge began rapidly to decrease, ceasing entirely in three or four days, and there has been no return.

Dr. Swain, in commenting upon the result obtained in Dr. Rhodes' case, considered that just as successful a result might have been obtained by the use of any agent, such as electricity, etc., if it had been used to the required degree, since it was the profound systemic disturbance which produced the cure in the case reported.

Some Remarks on the Intranasal Surgery of To-day.—Dr. J. N. Mackenzie of Baltimore read a paper with this title. Its general tenor was that of a protest against many of the radical methods now in vogue. They were pursued by some operators with a most indiscriminate zeal, and were calculated to bring the modern surgery of this region into disrepute. One reason for this *furor secandi* was the fact that the interior of the nose would stand a great deal of mutilation without dangerous reaction, but this was no justification of the courses so often followed. The author believed in thoroughness when operations were justified, but he could not accept as valid some of the arguments advanced to justify operations done at the present time on the nose and accessory sinuses. Too much stress had been laid on the effects of slight septal deviations, and often the sequelæ of operations left the patient in a far worse condition than before. He thought that if the statistics of all operations done could be placed before us and not those merely of favorable results we would be appalled at the showing. The relief from the present condition of affairs was to come through a better education of the rising generation of laryngologists.

A Study of the Fatal Operations upon the Nose and Throat.—Dr. Francis R. Packard presented a paper with this title. He regarded it as surprising that so few fatalities followed in this class of operations, considering the frequency with which they were done. He presented tabulated lists of the fatalities recorded in literature. He was able to find twenty-six fatalities following from anæsthesia, twenty-four from chloroform, one from the A. C. E. mixture, and one from ether, the latter apparently from bronchitis. Chloroform deaths followed with especial frequency in those patients who presented the status lymphaticus. Of fatalities due to causes other than the anæsthetic he had found twenty-two. Of these fourteen were from hemorrhage after removal of tonsils and adenoids. Other causes were meningitis from application of perchloride of iron for epistaxis, purulent leptomeningitis following operation by external incision for removal of nasal polyps and orbital tumor. Meningitis following cauterization with galvanocautery of the middle turbinate, meningitis following probing and injection of the lacrymal canal and the same disease after removal of an exostosis, and one death from sepsis and exhaustion following tonsillotomy.

Observations on the Therapeutic Value of Medicated Ointments in Certain Affections of the Nasal Chambers.—The paper of Dr. Alexander W. MacCoy of Philadelphia is summarized as follows: "(1) Notwithstanding the bent of mind toward surgical procedures for the relief of diseases of the nasal chambers, the rational employment of drugs must still keep our attention. (2) Our constant and persistent use of nasal washes, especially during the winter season in our climate, tends to harmful results

(3) By the employment of curative medicaments in the form of soft ointments in the nasal chambers we can avoid certain risks following the use of washes, etc. (4) The availability, convenience, and adaptability of medicated unguents in the therapeutics of the nasal chambers appeal in a rational manner for their employment. (5) Ointments prescribed should be dispensed in collapsible tin tubes, as this renders them most convenient for use at all times and in all places."

Dr. H. L. Swain, believed there was a definite field for the use of preparations containing oil in one or another form in the treatment of the acute affections of the nose. He stated that with regard to the different drugs and their chemical affinity, he had often prescribed the yellow-oxide ointment and found that when the patient was at the same time taking potassium iodide, there was a combination of the drugs with a very unpleasant reaction of the two. He called attention to this chemical affinity since he had never seen it stated in print, and because if he had known of it earlier it would have been of great service in saving much trouble.

Dr. J. Solis-Cohen of Philadelphia suggested the use of what is known as a "stripping pencil," placing the ointment upon the end of this and then pushing it backward into the nose until it reaches the thorax, when it is brought forward and out, having in this way touched the entire mucous membrane. These pencils are used for painting the colors in carriage wheels and are about an inch long.

Dr. W. K. Simpson of New York stated that he had experienced difficulty in applying ointments of sufficient density, but thought that if this could be done, the medication by ointments would be an ideal form of treatment.

Dr. G. Hudson Makuen of Philadelphia called attention to the danger of using ointments, citing the case of a patient who formed the bad habit of applying vaselin to his nose before retiring in order to keep the mucous membrane moist, and thus allowing of his spending a comfortable night. He has continued this application for eight or ten years, so that now he has formed the habit and is unable to break himself of it.

Dr. MacCoy, in closing the discussion, advised the application of ointments being made by covering the ends of toothpicks or matches with cotton to serve as carriers, and after these are once used they are to be thrown away. He regards this as a method which is suitable for business, traveling, etc. With regard to the amount of ointment applied, he stated that it was of no consequence whether this was great or little, nor whether thick or liquid. He himself never uses strong or severe ointments on account of the irritation produced by their use.

The Etiology and Diagnosis of Ozæna and Its Relation to Pulmonary Tuberculosis.—Dr. Clement F. Theisen of Albany read a paper with this title and with the following conclusions: "(1) Sinus disease probably causes ozæna in a certain percentage of cases, or at least it must be considered a strong predisposing cause. (2) Suppurative processes in the accessory sinuses, as shown by Pearce's observations, are frequently present in certain of the infectious diseases of childhood, particularly scarlet fever, measles, and diphtheria, and for this reason these infectious diseases must be considered at least possible etiological factors of ozæna. (3) That while a certain percentage of cases are caused by sinus disease this is not sufficient to explain the pathogenesis of the whole clinical picture of ozæna. (4) The large number of ozæna patients having pulmonary tuberculosis would certainly point to the nasal condition as a strong predisposing cause for the development of the tuberculous condition."

Dr. J. L. Goodale of Boston stated that there were many and various conditions known as ozæna, and that all are practically identical in treatment.

Dr. Thomas J. Harris of New York stated that in a study of nineteen cases of genuine ozæna which he examined for sinus disease he discovered antrum disease in two, it being unilateral in each, and in a third case he found an ethmoidal sinus affection. Other than this he was unable to recognize any sinus complications. Regarding the relation between tuberculosis and ozæna, Dr. Harris stated that in an examination of twelve cases he found only one showing a condition of tuberculosis, and this patient had laryngeal tuberculosis when he presented himself for treatment for the ozæna. Reference was made to Hamilton's statistics regarding this matter. Hamilton, in an examination of one hundred cases of tuberculosis found no ozæna, but in fifty cases of tuberculosis he found the tubercle bacillus. In 170 cases of ozæna he discovered but six cases of tuberculosis. Dr. Harris calls attention to the difference between the statistics of Dr. Theisen and Dr. Hamilton. Reference was also made to the statement by Ingals, that ozæna occurred less often in proportion than the average of nasal diseases in relation with tuberculosis.

Dr. Cornelius G. Coakley of New York stated that it had been the rarest thing in his experience to find cases of typical disease of the accessory sinuses accompanied by those conditions regarded as ozæna. He condemned the Jackson apparatus for transillumination as being practically useless. He also deprecated the use of strong antiseptic solutions in the treatment of this condition, believing that the employment of simple astringent fluids was productive of good results.

Dr. Emil Mayer of New York referred to the statistics of Pearce with regard to empyema in young children. Reference was also made to eight cases of his own, from the study of which he believed that an infection of the accessory sinuses in young children does bring about ozæna.

Dr. J. Payson Clark of Boston had examined one hundred cases of tuberculosis of the larynx, studying them particularly with regard to the nose, and had compared with them one hundred cases coming to the clinic with other troubles, and was struck with the great proportion of cases of ozæna and atrophic rhinitis in the cases which had tuberculosis of the larynx as compared with those having no local trouble.

Dr. James E. Newcomb of New York referred to having examined seventy cases of tuberculosis without finding one case of ozæna among them, taking the term of ozæna to signify a foul-smelling discharge. There were seven or eight cases, however, in which the patients had atrophic conditions of the nose. It is thought that the generally bad environments of these patients is somewhat to blame for these conditions.

Dr. H. L. Swain of New Haven stated that he had not found the occurrence of sinus disease any more frequent among his ozæna cases than among others. He considered it very reasonable, however, that tuberculosis should be associated with ozæna, since this condition presented a good chance for the growth of all kinds of bacilli.

Dr. Thomas Hubbard of Toledo considered the coexistence of tuberculosis and ozæna as a mere coincident. Attention was called to the feature of temperature in tuberculosis, since this naturally meant the drying of all mucous membrane and the production of a slight atrophic condition, which would naturally tend toward a condition from which it would be very difficult to differentiate ozæna.

Dr. William Lincoln of Cleveland cited three cases in which, subsequent to an operation, a very low condition of the general health and the appearance of ozæna, developed. The ozæna yielded, however, to the restoration to good health of the patient. He therefore lays stress upon the point that one should not endeavor to fasten the cause of ozæna upon any one disease, but should keep steadily in mind that any vastly depleting disease may be followed by this condition.

Dr. W. E. Casselberry of Chicago gave it as his opinion that a conclusion with regard to this subject would never be reached until the term ozæna was either done away with or defined more correctly.

Four Unusual Tumors in the Nasopharynx—Dr. Walter F. Chappell of New York briefly reported these cases. The first patient was a girl fifteen years of age, who, for about four years, had had difficulty in breathing, growing worse at night. On examination, the right nostril presented a whitish growth, protruding anteriorly within an inch of the anterior nares. A large reddish mass was found in the nasopharynx, extending below the free margin of the soft palate, and completely filling the nasopharynx. This was removed with an adenoid curette and slight hemorrhage occurred. This mass was found, on microscopical examination, to be an œdematous polypus. After its removal respiration was restored, and the patient gained in weight. The second case was that of a boy fifteen years of age, who complained of a full feeling in the back part of the throat, nasal stoppage, and choking sensations at night. On examination, a large gray, granular-looking mass was seen to extend one and a half inches below the soft palate on the left side. The patient's hearing was not impaired, he complained of no pain, and his general condition was good, although his sleep had been so much disturbed that he felt quite exhausted. The mass was removed through the mouth with a pair of forceps, and was found attached by a pedicle about one-eighth of an inch and one-sixteenth of an inch thick. A careful examination showed the tumor to have sprung from the lateral tonsillar region.

Dr. Emil Mayer of New York reported a case of unusual postpharyngeal growth in a man thirty-two years of age, who presented very slight symptoms, but who showed the glistening tumor in the pharynx extending into the nasopharynx. This was removed and proved to be a pure nasal polypi.

Dr. James E. Newcomb of New York reported the case of a patient who had been unable to breathe through the nose for five years. It was supposed that she had a nasopharyngeal fibroma, and an operation was advised. Several small bands of connective tissue were removed, and it was then found that there was no tumor at all.

Facial Asymmetry as a Cause of Deformities of the Nasal Septum.—Dr. Henry L. Swain of New Haven gave an extensive résumé of the work done on the skulls in the Marsh collection in Peabody Museum at Yale University, during the past three years. This work was carried on for the purpose of determining the cause of the over-arching of the palate, which is so frequently seen. Cases were presented relative to the subject, and comparisons made between the adult Hawaiian and young Hawaiian, the young flat-head Indian, and the adult Flat-head Indian. In this comparison, the measurements of Dr. J. H. Hurst were used. The question of heredity was extensively considered.

Dr. Thomas Hubbard of Toledo referred to the casual observations which he had made of the heads of a particular family. The parents had perfectly healthy and normal dental arches. Three out of their eight children had developed deformed arches. In one child the arch was very decidedly deformed, the palate elevated, and the dental arch completely broken, so that the teeth were irregular; in this case one of the incisor teeth penetrated the arch in almost the median line of the mouth. In the third generation one child had teeth which appeared at irregular intervals, the dental arch being so entirely broken as to crowd out the teeth. These cases were cited to show the effect of heredity in the development of the arch of the palate.

Dr. John O. Roe of Rochester discussed the question from the standpoint of heredity, mentioning the law of compensation. He referred to cases seen by him in which adenoids have been the cause of deflected septum.

Dr. A. Coolidge, Jr., of Boston referred to the cases reported at the meeting of the association in New Haven, in which there was congenital occlusion of the posterior opening by a bony plate. He stated that, if there ever was a case in which mouth-breathing ought to affect the shape of the skull, or in which breathing through one side of the nose should affect the skull, the cases referred to were such, but these cases did not show any particular tendency to high arch or deviation of septum. It was his opinion that if such complete occlusion of the nares did not cause high arching of the palate, adenoids were still less likely to do so.

Intratracheal Injections.—Dr. Thomas Hubbard of Toledo, Ohio, read a paper with this title in which he awarded the claim of priority of this method to Botey, who had presented clinical reports of cases before the Academy of Sciences of Paris, in 1890. It was stated that it was the general impression that the method of Botey had not been adopted as a routine practice by laryngologists in general. The author believed, however, that it was only through familiarity with the method that one could appreciate its superiority over other methods in common use. Among the American writers who had advocated the method and enlarged its field of practical application, were mentioned Thompson, Murray, Anderson, Simpson, and Donellan. It was admitted by Thompson and others that injections did no good, and might even do harm during the acute hyperæmic stage of any type of inflammation. The fact that a patient was expectorating freely was no indication that the injections should be used. The treatment of tracheal injections was essentially local, the purpose being to encourage free secretion and to prevent the fermentation or decomposition of accumulated deposits and the formation or production of sapræmia. Tracheal injections were considered as very useful adjuvants to the general treatment of bronchial asthma. The technique had not been considerably altered since that described by Botey. The long curved laryngeal cannula attached to the Muir syringe seemed to be the favorite instrument. Cocaine anæsthesia was used prior to injections as a routine practice. Although there were some cases in which intratracheal injection was useless, the majority of cases were relieved of discomfort. The author advocated the use of a modified cannula having a half-inch bend, which was, however, not long enough to reach below the tip of the epiglottis. He had found the treatment by intratracheal injections useful not only in bronchitis, but also in laryngitis, not including the acute hyperæmic state. The efficiency of this method appeared superior to that of the swab or spray.

Dr. J. W. Gleitsmann of New York referred to his use of intratracheal injections, stating that one patient had been entirely relieved, and that, although another had been greatly helped during the administration of the treatment, the old condition had again returned. He believed that the use of the laryngeal mirror was necessary in order to introduce safely the long cannula which he considered necessary for this treatment. He had frequently used the intratracheal syringe, and had seen many good results and great improvements. In the injections he confined himself to the use of bengaline and camphor, having found this productive of good results.

Dr. W. K. Simpson of New York considered intratracheal injections to be one of the most positive means of both local and constitutional effect upon the bronchial and pulmonary conditions, and believed that they would soon become a very popular mode of treatment. He stated that a considerable amount of technique was required, before its use was satisfactory. He related the case of a very robust man, in whom a pneumonia developed after the use of the intratracheal syringe.

Dr. Emil Mayer of New York did not think sufficient stress had been laid upon the temperature of the injected fluid, it being his opinion that this should be of the same temperature as the throat into which it was injected.

Dr. John O. Roe of Rochester suggested the use of chloroform prior to making the application by the intratracheal syringe, considering this a much better agent for the purpose than cocaine.

Dr. G. Hudson Makuen of Philadelphia said he believed that if one could avoid touching the epiglottis, no

spasm would be produced. He referred to a cannula devised by Dr. Freer of Chicago, which he had used with most satisfactory results, much preferring it to the intratracheal syringe.

Dr. J. L. Goodale of Boston agreed in the statement of Dr. Roe, that the use of cocaine, especially in those cases in which frequent application was necessary, was to be deprecated. He mentioned a combination which he had used, of a saturated solution of eucain B, in a little adrenalin. This solution nearly equalled cocaine in the completeness and rapidity of its action.

Dr. Hubbard, in closing the discussion, stated that he considered the question of anæsthesia of the larynx of small importance, since, if the small, sharp curved cannula was used, the tip did not even touch the epiglottis, and with a properly placed laryngeal mirror, fluid could be injected into the trachea in all cases in which one could see the glottis, or below it. Regarding the temperature of the fluid injected, he stated that at first he was careful to have this fluid about the temperature of the blood, but that of late he had disregarded this precaution, using it at about the temperature of the room, and had been surprised at the excellent manner in which it had been received.

The Compensatory Action of Certain of the Laryngeal Muscles Seen in Cases of Vocal Disability during the Past Year.—Dr. Clarence C. Rice of New York summarized his paper, as follows: "(1) There exists throughout the entire muscular system of the body, the intention and the habit of one group to render assistance to any other group of muscles which may be temporarily, or permanently, inefficient. (2) Compensatory service is more readily appreciated in the larynx than elsewhere, because its technique may be observed with the laryngeal mirror. (3) The weaker of the laryngeal muscles are very easily fatigued by too rapid action or by overtraining, and that it is the habit of the stronger muscles to offer their assistance immediately. (4) Although this compensatory action is wonderful from a physiologic point of view, it is unfortunately accomplished at the expense of any great success in singing."

Dr. G. Hudson-Makuen of Philadelphia said that the great difficulty in diagnosing faulty laryngeal action, lay in the fact that the laryngoscope would not permit one actually to see the action of these muscles, during the singing process. He considered it important that this subject should be given the attention which it deserved, and that then the singing profession might become aroused to the fact that laryngologists did not know anything about the subject, and were able to furnish them with plans or theories which would be of use. He then called attention to the training of the extrinsic muscles of the larynx, saying this training should be uniform, developing the weak ones and adjusting their action.

Dr. Rice, in closing the discussion, urged that the matter of laryngeal troubles should not be forgotten in the great interest taken by the association in nasal and pharyngeal work. He agreed with Dr. Makuen, that the laryngoscope was unsatisfactory in the study of the muscles during the singing process, but looked forward to the time when this might be possible. He believed that it was the laryngologist's province to watch the muscular mechanism of the larynx, in order to see whether it was doing good or bad work, and when the latter was noticed, then to set both pupil and teacher right. The teacher knew something was wrong with the voice, but was unable to explain the cause.

The Sequel to a Case of Post-typhoid Perichondritis of the Larynx, Reported to this Association in May, 1903.—Dr. Emil Mayer of New York presented the final report on this case (see page 446.

Dr. W. K. Simpson of New York stated that he hoped to present a case of this character before the association at the next meeting. With regard to the type of tube used in such cases, he suggested the use of the hard rubber tube in preference to the metal one, since there was less likelihood of occlusion by mucus in the rubber tube.

Dr. A. W. de Roaldes of New Orleans spoke of the danger of wearing a tube, referring to the case of a patient who was obliged to wear an O'Dwyer tube for several years, it being removed about once a month and cleaned. The greatest danger in this case was the collection of mucus in the tube. It finally became necessary to do a tracheotomy, and the patient was now wearing a tracheotomy tube, and was a strong, vigorous boy.

Dr. Mayer, in closing the discussion, stated that in cases in which tracheotomy has previously been performed, the danger of wearing a tube was not nearly so great. He regarded as the greatest danger the possibility of the sides of the larynx contracting, when the tube was removed.

Second Day—Friday, June 3.

Neuroses of the Upper Air Track, Exclusive of Those Due to Diphtheria and Organic Disease.—Dr. G. Hudson Makuen presented a paper dealing especially with "Neuroses of the Nose," in which he stated that neuroses of nasal origin had been divided into two general classes, the sensory and the reflex neuroses. The former class consisted chiefly of disturbances of olfaction—anosmia, hyperanosmia, and parosmia, and of disturbances of sensation—anæsthesia, hyperæsthesia, and paræsthesia. Anosmia might be due to various causes; there were three distinct kinds—the respiratory, the gustatory, and the essential. Basic tumors of the brain, meningitis, and tabes had been mentioned as causes of anosmia, and rheumatism might also be so considered. The absence of smell for certain things was not of unusual occurrence. Hyperosmia, or a genuine hyperæsthesia of the sense of smell, might be a forerunner of anosmia. It was often due to the excessive irritation of the olfactory nerve, and anosmia or paræsthesia of the sense of smell, might be due to constitutional conditions such as gave rise to digestive disturbances, or might be the result of local conditions, such as carious teeth, ozæna, or suppuration in the nasal and accessory sinuses. With regard to the operative measures suggested for the relief of nasal reflex neuroses, he stated that if they did not cure the disease, they at least add to the comfort of the patient, and render him less liable to future respiratory troubles of various sorts.

The author reported the case of a young man coming under his care, who suffered from epileptic attacks. Examination of the nose showed an irregularly shaped septum, with marked pressure in the region of the posterior third of the middle turbinate, on the left side of the right nostril. There was also a decided nasal and postnasal catarrh. Local treatment was advised and was followed by the removal of a large exostosis of the septum, which was pressing firmly against the left middle turbinate. After the operation the patient reported having had two slight epileptiform attacks, and on examination it was found that the packing introduced after the operation, was producing more pressure than was thought. With the removal of this pressure the epileptic condition subsided.

Dr. F. E. Hopkins of Springfield spoke of "Neuroses of the Pharynx." The author considered this subject under the heads of abnormalities of sensation, neuralgia, reflex neuroses, spasmodic disturbances, and vascular neuroses. In discussing the question of abnormalities of sensation, anæsthesia, hyperæsthesia, and paræsthesia of the pharynx were described: under reflex neuroses, tinnitus aurium and sialorrhœa. The author cited a case of Lambert Lack appearing in the *Laryngoscope* of June, 1898, as an illustration of spasmodic disease. It was stated, with regard to the treatment in nearly all the cases of pharyngeal neuroses, that the patients were neurotics, and that while local lesions were to be sought for and removed when found, the general health should be improved by every method which could be brought to bear upon the individual case.

Dr. Emil Mayer spoke of "Neuroses of the Larynx." After presenting a schematic drawing showing the dis-

tribution of the laryngeal nerves, he said that he had noted an interesting condition of affairs with regard to essays on the various neuroses of the larynx, in a retrospect of the twenty-five volumes of transactions of the American Laryngological Association. In the first fifteen volumes there were from three to four essays on this subject each year, while in the last ten volumes many years had elapsed without a single article on the subject. This was accounted for by the fact that those were the early days of the laryngoscope, and the functions of the larynx were being studied from every point of view, while in later years, with the advance of surgery in this and adjacent fields, newer observations were made in other directions, while few new facts presented regarding neuroses. The writer passed briefly over the various sensory disturbances, as hyperæsthesia and anæsthesia, and presented for discussion, first, spasmodic affections of the larynx. Among these were included laryngismus stridulus, congenital stridor, spasm of the glottis, chorea of the larynx, laryngeal nystagmus, and dysphonia spastica. Regarding congenital stridor in infants, the writer was inclined to agree with Thompson and Logan-Turner, that it was a neurosis. The second part of the discussion referred to stammering; the third part to neuralgia of the larynx; the fourth to status lymphaticus and sudden deaths. Regarding this, he said that the importance of a clear understanding of this subject could not be overestimated, as it would help to an explanation of the sudden deaths from anæsthesia in operations for adenoid growths. Among the motor paralyses, some unusual etiological factors were mentioned, such as paralysis due to pericardial exudate, mitral stenosis, postoperative (the removal of angiofibroma at the angle of the jaw, and laryngofissure for papilloma); and traumatism from bullet wounds. The treatment of functional aphonia was then considered, and finally hysterical aphasia.

Dr. J. H. Bryan of Washington said the subject of neuroses of the upper air passages was one of the most difficult problems with which laryngologists have to deal. He reported two cases of anosmia. In regard to laryngismus stridulus, he believed this undoubtedly to be a neurosis due in many cases to mechanical causes, and called attention to a case already reported, in which the condition was due to the falling of the epiglottis

Dr. Theisen of Albany referred to three cases of thymus disease recently seen in the Children's Hospital in Albany. These patients went to bed apparently perfectly well, but were found dead in the morning, having died without giving any warning whatever. It is believed one of these patients had several attacks of laryngismus stridulus.

Dr. J. W. Farlow of Boston considered the most troublesome cases to be those of neurosis of the nose accompanied by enlargement of the middle turbinate bone, a great deal of lacrymation, and swelling about the eyes. He suggested treating such cases by exercising the skin and by hydrotherapeutics. Mention was made of the great fear which patients suffering from spasm of the glottis had with regard to eating, fearing that they might swallow too large pieces, and therefore making a habit of taking but small portions. But it was much better for these patients to eat larger pieces in order to keep the passage open as wide as possible, and also because not so much irritation is caused when a medium-sized portion was swallowed as when the muscles had to contract around a small piece. Reference was made to a case in which the false and vocal cords would come together with such violence on any attempt at speech that the patient would be rendered almost unconscious.

Dr. John O. Roe of Rochester referred to several cases in which migraine, headaches, etc., were found to have been caused by small polypi. He advised that a careful examination of the nose should be made in such cases before any treatment was resorted to. With regard to the subject of chorea he cited the cases of two children having large tonsils and adenoids, and suffering from chorea. Upon the removal of the tonsils and adenoids, however, the choreic symptoms disappeared.

Dr. J. W. Gleitsmann of New York referred to the subject of nervous cough, reporting a case under his care which was cured by sending the patient upon a sea voyage. Upon her return home her general condition was much improved, and the cough which was of a purely neurotic character, had entirely disappeared. Dr. Gleitsmann said that polypi of the nose complicated by asthma, the latter condition being cured by the removal of the adenoids, was by no means of rare occurrence.

Dr. Thomas Hubbard of Toledo, Ohio, regarded the subject under discussion from a medicolegal standpoint, reporting a case in which he was compelled to give testimony. The patient had received a blow upon the back of the head on falling from a street car. Symptoms of a moderate degree of concussion developed, and the olfactory bulb was either lacerated or injured. With reference to laryngismus stridulus, Dr. Hubbard considers this a disease in which the prognosis should be very guarded, and in which the case should be carefully watched, since death frequently resulted when one least expected it. He also referred to a case of congenital stridor, in which improvement took place upon the removal of the tip of the uvula.

Dr. Thomas J. Harris of New York cited the case of a trained nurse who developed attacks of spasm of the larynx as a result of very much reduced general health. She had the characteristic attack coming on in the middle of the night, and the fear that she would die. There was no organic trouble, but there was very marked postnasal catarrh. The use of bromide of potassium was most successful in this case.

Dr. S. W. Langmaid of Boston reported the case of a young girl who suffered from a barking cough, and the condition was much improved by carrying out the method of suggestion; that is, it was suggested that if the patient would keep her mouth firmly closed the bark could not escape. This condition was considered to be very rare.

Dr. William Lincoln of Cleveland mentioned a case of chorea produced by the removal of a lymphoid growth from the pharynx.

Dr. W. K. Simpson of New York called attention to the results in a case in which the uvula was removed without the consent of the child's parents. The uvula was removed so completely that the patient developed a most marked case of general hysteria, becoming completely helpless, and unable to walk. The laryngologist was removing an enlarged tonsil in this patient, and considered the uvula was long enough to call for amputation. This nearly led to a suit for damages, however, on the part of the child's parents, and if they had taken the matter into the courts they would, doubtless, have won their suit, since their consent had not been obtained before the removal of the uvula which resulted in such distressing symptoms.

Dr. W. F. Chappell of New York referred to two cases coming under his observation in which during the premenstrual period the patients had intermittent attacks of laryngitis, and occasionally complete stoppage of the nasal passages, with some moderate amount of sneezing. Both cases were cured by hydrotherapy, the patients standing in warm water while the back was showered with cold water.

Dr. Clarence C. Rice of New York mentioned the fact that, in his experience, very stout people had been troublesome patients, and he concluded that the size of the pharynx bore a distinct relation to its influence upon the condition of the larynx.

Dr. G. Hudson Makuen, in closing the discussion said that treatment of neuroses of the nose by hydrotherapy would seem to him to be treatment of only the peripheral condition. In reference to the case of nervous cough reported by Dr. Gleitsmann, Dr. Makuen

cited a case in which the symptoms of cough and asthma were caused by a large thickened spot of mucous membrane on the posterior wall of the pharynx. After the cauterization of this spot the symptoms disappeared, and the patient entirely recovered. It was admitted that one might often cure the cause of nervous cough without curing the cough itself, since if the patient had formed the habit of coughing it was very hard to break him of it. A case was related of laryngeal vertigo cured by removal of the tip of the uvula, which was very long.

Dr. Emil Mayer called attention to the fact that vertigo sometimes existed in connection with neuroses of the nose. He said nervous cough was a very rare condition, although reflex coughs were stated to be not unusual, and were often cured by treating the lingual tonsils, or by curetting the posterior pharyngeal wall. Reflex coughs, however, were not considered by Dr. Mayer to be strictly nervous conditions. In referring to the case of congenital stridor due to an elongated uvula, Dr. Mayer stated that many men maintained that this condition was not a neurosis, but in this connection he consulted with a number of pediatric physicians, and most of them agreed that it was primarily a neurosis. In regard to Dr. Rice's statement that laryngeal spasm was frequently met with in stout people, Dr. Mayer stated that this had not been his experience.

Removal of Foreign Bodies from the Œsophagus and Bronchi by the Aid of Killian's Œsophagoscope and Bronchoscope.—Dr. E. Fletcher Ingals of Chicago reported two cases. The first case was that of a child about two and a half years of age who swallowed a fleur-de-lis chatelaine pin. A radiograph showed the foreign body located at the inner part of the œsophagus just above the interclavicular notch. The child had swallowed the pin six days before being seen by Dr. Ingals, and during that time had suffered from severe nausea and had been unable to take solid food. The patient was given chloroform, and Killian's œsophogoscope, illuminated by Kirstein's lamp, was introduced. The pin was discovered in the folds of the collapsed œsophagus at the end of the tube. It was impossible to remove the pin through the tube, on account of its size, and therefore both the tube and the pin were brought out together. The second case was one of the removal of a pin from the lung. The patient was a girl of seventeen, who presented a history of having drawn a large glass-headed pin into the air passages eleven months previously. For three days following the accident she had attacks of cough, but the symptoms were so slight that no action was taken The cough, however, grew gradually worse, and at times the pin could be felt to move about in the air passages, and at one time it was coughed up to the larynx,when it caused a spasm which nearly resulted fatally. Her sensations had always been referred to the right side or to the center of the sternum. She was short of breath, particularly upon lying down. Large quantities of sputum, sometimes containing blood, had been expectorated. The *x*-ray was used three times but showed nothing. The trachea had previously been opened in an attempt to find the pin, but this proved unsuccessful and the wound was therefore closed and healed rapidly. It was stated that an abscess had been found at the time of this operation and that there was considerable expectoration of pus. When the patient came under the writer's care she was coughing a great deal and expectorating from three to six ounces of mucopus daily. A radiograph was taken showing the pin on a line between the second and third ribs in front and the fifth rib and sixth interspace behind, and from 3 to 4½ cm. to the right of the median line with the head directed downward and outward. The patient was given chloroform, and after much difficulty the pin was extracted with the bronchoscope. The patient recovered from operation promptly, and is now in better health than before the accident.

Dr. J. Edwin Rhodes of Chicago mentioned a case in which a pin, similar to that extracted by Dr. Ingals in the second case reported, had been removed by him through a tracheal opening from the third tonsil.

Dr. W. K. Simpson of New York reported a case in which a pin had been swallowed, lodging in the œsophagus. The *x*-ray showed it turned with the point up so that it was impossible to remove it. During the night, however, the pin became inverted and was extracted under chloroform anæsthesia.

Dr. John O. Roe of Rochester reported the removal of a twenty-five-cent piece from the œsophagus of a child of eight years. The exact location of the coin was determined by the use of the *x*-ray, and it was then extracted by the aid of a special forceps devised by the speaker.

Foreign Bodies in the Bronchus.—Dr. A. Coolidge, Jr., of Boston, supplemented Dr. Ingals paper by reporting four cases. In three cases a preliminary tracheotomy was performed, and in the other the foriegn body was removed by the aid of Killian's bronchoscope. The first case reported is that of a man who had lost a silver dime in his nose, it having fallen into the trachea. A low tracheotomy was done, but attempts to seize the coin were unsuccessful. There was no discomfort in breathing. The *x*-ray showed the coin to be situated just to the right of the median line at the fifth costovertebral articulation. The patient was placed on his back without a general anæsthetic, a straight speculum was introduced through the tracheal wound and pushed down nearly to the bifurcation. The coin was seen in the upper part of the right bronchus and removed with alligator forceps. The second case was that of an infant of twenty-two months, who twelve days before admission, after having been left alone, was found choking and cyanosed. On admission nothing abnormal was found on percussion or auscultation. There was an occasional spasmodic cough. A shawl pin was found to be lodged in the right bronchus and was removed with alligator forceps. The third case was that of a woman who had swallowed a pin 1½ inches long. On examination the pin was found to be at the fourth interspace on the left side and the head directly below it. An unsuccessful attempt at removal was made with Killian's bronchoscope. The following day the pin was shown to be in the same place, and on the third day, without a general anæsthetic, the trachea was sprayed with cocaine and a short tube inserted through the wound. The pin had become dislodged and was seen high up in the left bronchus and was easily removed. The fourth case was that of a boy aged eight years, who declared he had swallowed a nail, but this statement was not believed. A few days later the patient develloped a right-sided bronchitis. Examination with the *x*-ray showed a foreign body in the right bronchus. Under ether anæsthesia, Killian's bronchoscope was introduced and the nail seen projecting from the right bronchus into the trachea with the point imbedded in the tracheal wall. When the nail was touched coughing was excited and also a little bleeding. After two or three attempts the nail was withdrawn through the glottis with the tube, and was seized in the bronchus. Dr. Coolidge added that if he had had the experience in connection with his third case which he had with his fourth, and if he had had the instruments on hand for maintaining respiration for the right bronchus while he invaded the left, he would have made an attempt to reach the foreign body through the nasal passages before doing a tracheotomy. He stated that the introduction of Killian's autoscope was much easier in the living subject than in the cadaver, and believed it an instrument which could be used a great deal oftener than it now is.

The Present Methods for the Treatment of Malignant Diseases of the Larynx were considered by Dr. D. Bryson Delavan of New York (see page 441.)

Dr. E. Fletcher Ingals of Chicago thoroughly agrees with the author of the paper in regard to the operation of laryngectomy only being performed by qualified persons. Two cases were reported, in one of which a preliminary tracheotomy was performed, and in both of which a complete laryngectomy was done. The patients

made uneventful recoveries from the operations, and were able to talk very well.

Dr. H. L. Swain of New Haven also reported a case of laryngectomy, and this patient was also able to talk. He was a minister, and had voice enough to preach again if he so desired. There was no preliminary tracheotomy in this case, and except for a stitch abscess the patient made an uneventful recovery from the operation. Mention was made of the case presented by Dr. Chappell before the last meeting of the association. This patient would pass the three-year limit within two months and there was still no sign of recurrence.

Dr. John N. Mackenzie of Baltimore reported the case of a woman who presented herself to him having well-marked papilloma of the soft palate and posterior wall of the pharynx with spots of infection here and there on the lateral wall. This case was inoperable, and the patient was therefore advised to put herself under the care of Dr. Pusey of Chicago. The treatment by use of the *x*-ray was instituted, and was successful with regard to the growth in the pharynx, but the infection spread along the lateral wall deeper into the larynx until it reached the epiglottis. The case is referred to as an instance of the adaptability of the *x*-ray to the pharynx. Dr. Mackenzie thoroughly agreed with the author in the question of only having qualified men to perform the operation of laryngectomy.

Dr. W. K. Simpson of New York was convinced that the average laryngologist was not capable of doing excision of the larynx for cancer. He called especial attention to the lack of attention paid to the question of technique even by good operators, and cited a case resulting fatally from neglect of the post-operative technique.

Dr. William Lincoln of Cleveland considered that it was wiser to run the risk of operating before malignancy was thoroughly established than to wait until this was certain. In regard to the treatment of these cases by the *x*-ray, Dr. Lincoln referred to a case in which this agent was used with no result for good. Mention was also made of the seven cases reported by him in his thesis of last year, all of which were operated upon by Dr. Crile. Operation was undertaken in every case, not with the promise of cure, but with a view to relieving the pain and discomfort, and in six cases prevented many weeks of suffering. The other patient was completely cured.

Dr. Delavan, in closing the discussion, stated that with regard to the *x*-ray, the more superficial the growth the more probable was the prospect of relief, and said he believed this agent had been invariably used in cases of laryngeal cancer, the patient hoping thus to do away with operation. The treatment with this agent so far has been entirely from the outside. Dr. Delavan stated that he had had cases of inoperable tumors of the neck in which the *x*-ray had been of the greatest possible value in relieving the suffering. Stress was laid upon the danger of excising portions of malignant growths for microscopical examination. Thyrotomy was not considered justifiable in laryngeal cancer. Dr. Delavan referred to two cases which resulted fatally after complete laryngectomy, and one after a partial laryngectomy. In all these cases he believed the result would have been different if the operators upon the cases had been more skilful.

Effects of Tobacco upon the Throat.—Dr. Samuel W. Langmaid of Boston referred to the literature on the subject, and expressed his belief that the climate had much to do with the effect produced upon the mucous membrane of the throat by smoking. He was convinced that the nicotine carried to the throat of the smoker was in reality very small in comparison to the amount of carbon monoxide gas, and therefore attributed the poisonous symptoms produced by smoking to the absorption of this gas by the system. He believed that tobacco smoking was not only harmful to the throat as a direct irritant, but that it produced vasomotor disturbances of the pharyngeal mucous membrane by its poisonous effects upon the nervous system.

Dr. Swain of New Haven referred to a case of a young woman who complained of trouble with her throat. It was found that she was a smoker. Three years after the first examination of her throat, she returned for a second examination, but no appreciable difference was found in the condition. She complained, however, of having less comfortable nights, and this seemed to have been the only added symptom after three years of smoking. It was Dr. Swain's opinion that smoking left a certain mark upon the throat, which was, however, hard to define.

Dr. J. W. Farlow considered it the duty of laryngologists to instruct their patients as to the best way to smoke with a minimum amount of damage to their throats, and suggested that even one or two cigars might be smoked daily without harm, if taken immediately after the principal meal. The mouth should be rinsed out after smoking with cold water, in order to remove the sticky condition of the mucous lining of the nasopharynx and pharynx.

Dr. Langmaid had found that good results had been produced by having the patient give up smoking for a time. He stated that many of our best singers smoke, and that smoking had less effect upon the voices of low register than upon those which were higher, since the lower pitched voices did not depend upon the finer chords for their beauty of tone.

Bone and Cartilage in the Tonsil.—Dr. James E. Newcomb of New York presented a paper with this title. His attention had been called to the condition from reports of the few cases recently published, and some two years ago he had seen one case in his own practice. The patient was a woman of about thirty years, whose tonsils were enlarged. In removing the left one with the usual Mackenzie instrument a hard body was pierced, and examination of the tonsil after removal showed that the body was the tip of the styloid process of that side. The process was under normal conditions about 2½ cm. in length and projected downward, forward, and inward from the under surface of the temporal bone, being a derivative of the second branchial arch. In his own patient the right side presented nothing abnormal. Such cases were perhaps of greater interest than importance, yet irritation might result if sufficient soft tissue did not pad the stump left in the tonsil. His own patient had suffered no inconvenience, though the stump was easily perceptible on palpation. As to bony and cartilaginous nodules scattered throughout the tonsils, he had had very little personal experience. Several tonsils had come under his observation which showed masses too large and firm to be regarded as connective tissue, and he had surmised that these masses might have been cartilaginous, but this view had not been confirmed by the microscope. Two theories were held as to the origin of these cartilaginous deposits. According to one, they were vestigial rests of the second branchial arch, and were therefore to be looked upon as enchondromata. The other theory referred them to metamorphosis of connective tissue. It was difficult to say which theory was correct, as on embryological grounds there were arguments against the validity of either. We had to remember that cartilage might develop independently of the skeletal frame in the connective tissue of organs when mechanical relations demanded its presence. The writer of the paper presented a summary of the various views on the subject with brief reports of published cases.

Dr. Cornelius G. Coakley of New York stated that in his researches on branchial cyst in connection with his paper he was surprised to see how often cartilage and bone were found in these cysts. He also said that he found some bone on the anterior surface of the posterior pillar

of the fauces and some in the cellular tissue under the lateral wall of the pharynx.

Dr. JOHN O. ROE of Rochester reported a case in which he struck against a very hard substance while attempting to remove an enlarged tonsil with the snare. This osseous formation was found to be the end of the styloid process, which was projecting into the tonsil for nearly half an inch.

THIRD DAY—SATURDAY, JUNE 4.

The following papers were read, some of them by title: "Submucous Operations on the Nasal Septum; No Perforation—the End in View; Report of Cases," by Robert C. Myles, M.D., of New York. "Broncholiths, with Report of Case," by D. Braden Kyle, M.D., of Philadelphia. "The Final History of a Case of Supposed Vocal Nodule; Epithelioma of the Larynx; Thyrotomy; Death," by Charles H. Knight, M.D., of New York. "Subglottic Tuberculous Lesions of the Larynx," by T. A. DeBlois, M.D., of Boston. "Two Cases of Pemphigus of the Mouth," by John W. Farlow, M.D., of Boston. "A Branchial-cleft Cyst Simulating a Retropharyngeal Abscess," by Cornelius G. Coakley, M.D., of New York. "Primary Ulceration of the Tonsil, Together with Some Remarks on Tonsillar Ulceration in General," by Thomas J. Harris, M.D., of New York. "Tic Douloureux from Sphenoidal Disease," by John O. Roe, M.D., of Rochester. "Lupus of the Pharynx and Nasopharynx Cured by the *X*-rays," by Herbert S. Birkett, M.D., of Montreal.

During the executive sessions of the Congress, the following gentlemen were elected: To Corresponding Fellowship, Prof. B. Fraenkel, Berlin; to Active Fellowship, Dr. T. Passmore Berens, New York City. Title of thesis, "An Operation for the Correction of External Deformities of the Bridge of the Nose." Dr. John M. Ingersoll, Cleveland. Title of thesis, "A Study of the Development of the Nose and Its Accessory Cavities." Dr. Harris P. Mosher, Boston. Title of thesis, "The Applied Anatomy of the Frontal Sinus."

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Clarence C. Rice of New York; *Vice-Presidents*, Drs. Thomas Hubbard of Toledo, Ohio, and Walter J. Freeman of Philadelphia; *Secretary and Treasurer*, Dr. James E. Newcomb, New York; *Librarian*, Dr. J. H. Bryan, Washington, D. C.; *Members of Council*, Dr. D. Bryson Delavan of New York, to serve for three years, and Dr. J. H. Hartman of Baltimore, Md., to serve for four years. The date and place of the next congress were left to the decision of the council to determine. An amendment to the constitution was adopted increasing the active fellowship from seventy-five to one hundred.

Removal of Pin from the Lung, per Vias Naturales, with Bronchoscope and Tube Forceps.—E. Fletcher Ingals carefully describes this case. The pin, a large glass-headed one, had been swallowed nearly a year before. Tracheotomy was performed but the pin was not found. The writer gave $\frac{1}{60}$ gr. of atropine hypodermically to check secretions. Chloroform was administered, and when anæsthesia was nearly complete the larynx and trachea were sprayed with a solution of cocaine and suprarenalines with atropine, strophanthine, carbolic acid, and oil of cloves. He then introduced a Killian bronchoscope, 34 cm. long, through the larynx down into the right main bronchus and one of its larger branches. The parts were illuminated with a small Chicago-Electro Appliance No. 1 (cold) lamp, with carrier 33 cm. long, made for the special purpose. Careful search with a blunt hooklet was made for the pin for about three-quarters of an hour. Finally it was brought across the end of the tube, and was then caught with Killian's tube forceps. But not being able to extract it in this way, the writer finally regrasped it firmly and drew it and the bronchoscope out together. In doing so, the pin was bent to an acute angle near the head. The pin was of brass, 4 cm. long, and the glass head measured $5\frac{1}{2}$x8 mm. in diameter.—*The Chicago Medical Recorder.*

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE PRACTICE OF OBSTETRICS—Designed for the Use of Students and Practitioners of Medicine. By Dr. J. CLIFTON EDGAR. Second edition, revised. 8vo, 1153 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $6 net.

FRIEDBERGER & FROHNER'S VETERINARY PATHOLOGY (Authorized Translation). Translated and edited by M. H. HAYES, F.R.C.V.S. With notes on Bacteriology, By Dr. G NEWMAN, D.P.H. Volume I. 8vo, 519 pages, muslin. W. T. Keener & Company, Chicago. Price, $4 net.

A SHORT TREATISE ON ANTI-TYPHOID INOCULATION. By A. E. WRIGHT, M.D. 8vo, 76 pages, illustrated, muslin. Archibald Constable & Co., Ltd., Westminster. W. T. Keener & Co., American Agents. Price, $1.25 net.

SERUMS, VACCINES, AND TOXINES IN TREATMENT AND DIAGNOSIS. By WM. CECIL BOSANQUET, M.A., M.D., F.R.C.P. 12mo, 344 pages, muslin. W. T. Keener & Co., Chicago. Price, $2 net.

CLINICAL URINOLOGY. By Dr. ALFRED C. CROFTAN. 8vo, 298 pages, illustrated, muslin. William Wood & Company, New York. Price, $2.50 net.

CLINICAL LECTURES ON MENTAL DISEASES. By T. S. CLOUSTON, M.D., F.R.C.P.E. Sixth edition. 8vo, 738 pages, illustrated, muslin. Lea Brothers & Co., Philadelphia.

TRANSACTIONS OF THE SEVENTY-FIRST ANNUAL SESSION OF THE TENNESSEE STATE MEDICAL ASSOCIATION, CHATTANOOGA, 1904. 8vo, 424 pages, muslin.

THE MEDICAL EPITOME SERIES. SURGERY. A Manual for Students and Practitioners. By M. D'ARCY MAGEE, A.M., M.D., and WALLACE JOHNSON, PH.D., M.D. 12mo, 295 pages, illustrated, muslin. Lea Brothers & Co., Philadelphia. Price, $1 net.

A TEXTBOOK OF MATERIA MEDICA, INCLUDING LABORATORY EXERCISES IN THE HISTOLOGIC AND CHEMIC EXAMINATION OF DRUGS. By ROBERT A. HATCHER, PH.G., M.D. and TORALD SOLLMANN, M.D. 12mo, 411 pages, illustrated. W. B. Saunders & Co., Philadelphia. Price, $2 net.

A HANDBOOK OF SURGERY FOR STUDENTS AND PRACTITIONERS. By FREDERIC RICHARDSON GRIFFITH, M.D. 12mo, 570 pages, illustrated, leather. W. B. Saunders & Co., Philadelphia. Price, $2 net.

THE HEATH SCHOLARSHIP PRIZE ESSAY ON THE DEVELOPMENT AND ANATOMY OF PROSTATE GLAND. By W. G. RICHARDSON, M.B., B.S., F.R.C.S. 8vo, 121 pages, illustrated, muslin. J. & A. Churchill, London. Price, $3.75 net. P. Blakiston's Son & Co., Philadelphia, American Agents.

A TEXTBOOK OF DISEASES OF WOMEN. By CHARLES B. PENROSE, M.D., PH.D. Fifth edition, revised. 8vo, 550 pages, illustrated, muslin. W. B. Saunders & Co., Philadelphia. Price, $3.75 net.

THE PRINCIPLES OF HYGIENE. A Practical Manual for Students, Physicians, and Health Officers. By D. H. BERGEY, A.M., M.D. Second edition, revised and enlarged. 8vo, 536 pages, illustrated, muslin. W. B. Saunders & Co., Philadelphia. Price, $3 net.

PATHOLOGICAL TECHNIQUE. A Practical Manual for Workers in Pathological Histology and Bacteriology. By FRANK BURR MALLORY, A.M., M.D., and JAMES HOMER WRIGHT, A.M., M.D. Third edition, revised and enlarged. 8vo, 469 pages, illustrated, muslin. W. B. Saunders & Co., Philadelphia. Price, $3 net.

Those Who Sleep in the City of London.—Estimates framed by Dr. Collingridge for his annual report to the Court of Common Council place the number of those who sleep in the city at 24,958, and of those who are engaged in business there during the daytime at 358,930, of the 839 deaths registered in the district in 1903 no fewer than 631, which occurred in St. Bartholomew's Hospital, were of persons who had resided outside its boundaries.—*Daily Telegraph.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 12, 1904:

	Cases.	Deaths.
Measles	40	8
Diphtheria and croup	176	25
Scarlet fever	60	2
Smallpox	...	...
Varicella	2	...
Tuberculosis	391	139
Typhoid fever	146	21
Cerebrospinal meningitis	...	15

Radium and Temperature of the Earth.—Prof. Rutherford has stated that he believed the amount of radium present and uniformly distributed throughout the earth would be sufficient to account for all the heat lost from that body. In this event the cooling of the earth, so that it ultimately would become uninhabitable, as was calculated by Lord Kelvin, would be postponed, and a few million more years would be afforded for the various forms of animal life. Such a possibility was anticipated doubtless by Lord Kelvin himself, for in his calculations he inserted "provided no new form of heat is discovered." This is now held to exist in the minute quantities of radium which are widely and universally distributed over the earth, and which may account for the gradual increase of temperature as the interior of the earth is approached.—*Harper's Weekly.*

Annual Statistics Relating to Diphtheria from l'Hôpital des Enfants-Malades.—M.M. Marfan and Menard publish statistics concerning children treated in the diphtheria wards of l'Hôpital des Enfants-Malades between May 1, 1902, and May 1, 1903. The total case mortality upon 1,412 cases was 15.8 per cent. If those dying within the first twenty-four hours be omitted, the mortality is reduced to 11.1 per cent.; while if those dying during the first forty-eight hours be excluded, the mortality falls to 9.3 per cent. The authors note the following points: (1) A number of prophylactic injections were made in the case of brothers or sisters of those attacked. One thousand children received injections of 5 c.c. of serum for this purpose, and only two of them were attacked by diphtheria, one within twenty-four hours and the other four days after receiving the infection. Both cases were benign. (2) During this period diphtheria was less malignant than during the period which preceded it, but the cases of croup were more numerous. (3) Local treatment was reduced to a minimum, and was only carried out in the very offensive attacks with sloughing.

Bacteriology of Ink.—In 1901 there occurred in Switzerland several deaths of school children from blood poisoning, which was attributed to "repeated pricks from pens dipped in ink containing molds and other harmful bacteria." No very scientific investigation appears to have been made, however, either of the ink or of the bodies of the unfortunate children. The paternal Prussian Government was, nevertheless, alarmed, and Professor Flugge of Breslau was commissioned to investigate the matter. The results of experiments by his assistant, Dr. Heymann, are summarized in the *Hygienische Rundschau.* The various results occurring in ink had been previously studied by Marpmann, who showed that inks are usually sterile, owing to the tannic acid they contain. This was confirmed by Heymann, who found that out of twenty-four samples tested on glycerin agar culture media twenty-two were completely sterile, and the other two contained only "ordinary air bacteria." He further found that "gall ink" has considerable antiseptic powers, spores of penicillium being destroyed in twelve hours, and "the pathogenic" bacteria in an hour. He concludes that ordinary ink, either fresh or after prolonged use, contains no harmful microorganisms, and has a very great disinfecting power, especially against those which produce blood-poisoning. If pen pricks give rise to septic disease, it can only be through secondary infection.—*Medical Magazine.*

The High Mortality among Medical Officers in War.—Apropos to the Russo-Japanese war a Russian medical journal contains an article from which it appears that the rate of mortality among military surgeons was much larger during the war with Turkey than in the combatant portions of the army. As it was deemed of very great importance to know whether this was peculiar to the late war, a comparison was made with the ascertained losses of surgeons in former wars, and the following statistics are the result of this investigation: During the campaign in 1813-15 there were 2170 surgeons in the Prussian army, of whom about 10 per cent. were either killed or wounded, being in about equal proportion to the casualties among combatants. In the French campaign against Constantine, 1837, while every thirteenth combatant officer was killed, every sixth surgeon died. This, in proportion to the numbers, shows that the mortality among surgeons (16⅔ per cent.) was more than double that of the line officers (7⅙ per cent.). During the Crimean war, according to French official statistics, the mortality among the surgeons was 18.2 per cent. and among the combatant officers 7.3 per cent. In the last Russian campaign 355 surgeons out of a total of 2,839 died, being equal to 12½ per cent. In the Mexican expedition (French) the rate of mortality among the surgeons was about 20 per cent., while that of the combatant officers was only about 4 per cent. The only instance on record in which the proportion of deaths among combatant officers was larger than that of the medical officers was in the Prussian army during the Franco-Prussian war, '70-71.—*Journal of the Association of Military Surgeons of the United States.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended September 12, 1904:

OPERATIONS UPON THE EYEBALL IN THE PRESENCE OF AN INFECTED CONJUNCTIVAL SAC.*

By CHARLES STEDMAN BULL, A.M., M.D.,
NEW YORK.

SINCE bacteriology has become a science, the ophthalmic surgeon has learned that bacteria play an important part in all forms of suppuration following operations on the eye, for as a rule the infection comes from without. We all recognize that infection of the wound may occur during the operative act as well as afterward. It may come through the air, from the hands of the operator, from the irrigating solutions employed, or from the instruments used. It may be due to the conditions of the edges of the eyelids, or of the conjunctival sac, or of the lacrymal passages. The danger from aerial infection may be sufficiently guarded against during operations on the eye, to make it of secondary importance. The hands of the surgeon may be made aseptic by careful cleansing and scrubbing of the fingers, and the danger from this source is always slight, because in operations on the eyeball the fingers rarely come in actual contact with the tissues involved in the field of operation.

It is to be assumed that the greatest care is exercised in maintaining the absolute sterility of all fluids used in irrigating before, during, and after the operation, and of all collyria used. These, as well as the pipettes, should be boiled before using.

It is not always possible to be absolutely sure of the aseptic condition of our instruments, either because the fluids used for disinfecting them have not recently been sterilized, or because they may have become infected by the hands of the surgeon or assistants. This more especially applies to operations done at the residence of the patient.

This brings us to a consideration of the most important sources of infection, the edges of the eyelids, the conjunctival sac, and the lacrymal canaliculi and sac. Here is undoubtedly found the most frequent source of infection, for we can never be sure that the edges of the lids and the conjunctival sac are non-infected and sterile. They are the most dangerous sources of infection, for while it is possible that there may be no pathogenic germs in a normally appearing conjunctiva, we know that sometimes even in apparently sound lids and conjunctiva, the most virulent germs have been found. We have learned that we cannot with *certainty* make the edges of the lids and the conjunctival sac sterile.

The question then whether we shall operate on the eyeball when the conjunctival sac is infected is one of great importance to both surgeon and patient. At the first glance the subject would seem to occupy but a very narrow field, and not to admit of much discussion, but a closer study of the subject opens up the very wide field of bacteriology, which is practically limitless. One of the important facts taught us by modern bacteriology is that a normal conjunctival sac, free from noxious bacteria of all kinds, practically does not exist, or at least does not come within the ken of the ophthalmic surgeon. As far back as 1894, *Gayet* found, after disinfecting the conjunctival sac of his cataract patients, that microbes remained in 75 per cent. of them, and, from a study of 213 test-tube cultures, he concluded that antiseptic fluids have very little influence over germs in the conjunctival sac.

Rymowicz has given us a still more interesting report on the same subject. He investigated the conditions in one hundred healthy eyes. The conjunctival sac was cleansed with a sterilized physiological salt solution, and then the fluid from the sac was inoculated on agar with coagulated glycerinized beef serum. The conjunctival sac in every case was infected as follows: in 94 cases by the bacillus pseudodiphtheriticus; in 9 cases by the pneumococcus; in 5 cases by the streptococcus; in 6 cases by the Morax-Axenfeld bacillus; in six cases by the staphylococcus aureus; and in eight cases by the staphylococcus albus.

Another fact that the study of bacteriology has taught us is that the pathogenicity of microorganisms is by no means a constant quantity, but differs directly with their capacity to manufacture disease-producing toxins and tox-albumins. This capacity to manufacture toxins is influenced by certain natural and artificial agencies. Such agencies, for example, are unfavorable culture-media in the body, or conditions of life in which the germs are compelled to exist. Within the influence of such agencies, these toxins become attenuated or are not manufactured at all. Among the natural attenuating agents sunlight is most powerful, and among the artificial attenuating agents cleanliness, in the widest sense, is an all important factor.

Fick (Ueber Mikro-organismen im conjunctival Sack, 1887) found in fifty cases of apparently normal eyes only 12 per cent. without bacilli. He enumerates seven different varieties of bacilli and three kinds of cocci, among them the staphylococcus aureus and pyogenes.

A microscopical examination of the contents of the conjunctival sac should always be made before operation, as various microorganisms may cause very similar symptoms. For instance, the presence of disease of the lacrymal passages does not necessarily lead to the conclusion that the acute conjunctivitis is due to the presence of streptococci. Any pathogenetic bacillus of the conjunctival sac may become virulent when the conditions favor its development. But even after a careful microscopical examination, we are not always sure of our results, for the different bacilli vary in their destructive effects at different times. For example, the Koch-Weeks bacillus is apt to cause a distinctly contagious conjunctivitis with severe symptoms, while the conjunctivitis due to the diplococcus is usually not severe; and the conjunctivitis due to the diplo-bacillus of Morax-Axenfeld generally runs a mild and subacute course. Yet not infrequently these conditions

*Read before the American Ophthalmological Society, at its fortieth annual meeting, at Atlantic City, N. J.

are all reversed. The conjunctivitis caused by the staphylococcus and streptococcus is almost always marked by severe symptoms, among them the formation of a pseudomembrane, which is often with difficulty to be distinguished from a diphtheritic membrane, in spite of microscopical examination.

A brief study of a few of the more common forms of infection of the conjunctiva may help us to a conclusion as to when to operate, if at all, in the presence of infection.

There are several forms of conjunctivitis due to the streptococcic infection. The most common form is distinguished by marked engorgment of the conjunctival and subconjunctival vessels, slight secretion and slight swelling of the lids. Another form, due to the same microbic infection, shows a thin membrane or pellicle, and is called pseudomembranous. The common name of streptococcic conjunctivitis depends upon the abundant presence of the streptococcus in the secretion, and the impossibility of explaining the clinical symptoms without its intervention, though there may be other microbes associated with it, which do not explain the gravity of the inflammation. The false membrane is not always present, and is generally of extreme tenuity. There is always some swelling of the lids, and almost always a pre-auricular adenitis. The presence in the secretion of cocci disposed in chains does not prove it to be the streptococcus, for the pneumococcus does the same thing. The bacilli occur more frequently as disseminated diplococci, not to be distinguished from the staphylococcus and pneumococcus. There is no one pathognomonic symptom, but the general complex of symptoms will aid in the diagnosis, while a full demonstration is only furnished by cultivation and inoculation, and the bacilli should be numerous in the secretion and cultures. It should not be forgotten that the streptococcus, the staphylococcus, and the diphtheria bacillus may exist in the conjunctival sac without exciting any reaction, and infection can only occur in the presence of traumatism.

In operative cases the streptococcic infection is very grave, and generally leads to rapid perforation of the cornea and general suppuration of the eyeball. It is always difficult to trace the way in which this infection has occurred, or to determine the conditions which have facilitated its development. It is certain that in many cases the infection is developed in pre-existing forms of conjunctivitis, and it is probable that it would not have occurred without a preceding loss of epithelium. It is very doubtful if a streptococcic infection could be developed in a healthy conjunctiva, and we must regard it as a secondary inflammatory process.

Most of these cases doubtless come from the lacrymal sac, for there is usually slight redness and swelling over the sac and tenderness on pressure, and more or less swelling of the pre-auricular gland, and more rarely of the parotid and submaxillary glands.

The conjunctivitis due to pneumococcus infection is much rarer than that due to infection by the streptococcus or staphylococcus. It occurs mainly in young persons, and seems to be most prevalent in spring or autumn. Its appearance may be either sporadic or epidemic. It is sometimes met with in children with measles and bronchopneumonia, and here the symptoms are very severe, especially on the side of the cornea, which rapidly ulcerates, becomes deeply infiltrated, perforates, and ends in panophthalmitis and sometimes in the death of the patient. The pneumococcus seems to occur more frequently in certain localities. For instance, Rymowicz reports that in Kasan the pneumococcus conjunctivitis ranged from 18 per cent. to 36 per cent. of the cases, and was often accompanied by iritis and cyclitis, probably from development of toxins. In all the cases reported the pneumococcus has been found in great abundance in the secretion. At other times the symptoms are slight, the cornea is not involved, or if so, only superficially, and the pneumococci are few in number.

In the case of an infected lacrymal sac, the condition is somewhat more grave. The contents of a suppurating tear-sac are extremely infectious. It needs but a small wound in the cornea, the slightest injury to the corneal epithelium, to set up that most destructive process, ulcus serpens. Yet it is a well-known fact that many patients have suffered for years from suppuration of the lacrymal sac without any infection of the conjunctiva or cornea. Some two years ago, Stock (*Klinische Monattsblätter für Augenheilkunde*, 1902, p. 116) instituted some experiments on rabbits. The lacrymal sac was infected by the Bacillus pyogenus, Bacillus prodigiosus, and the Staphylococcus aureus, and he watched the animals for a varying length of time without result. He satisfied himself that the normal uninjured conjunctival sac of the rabbit could not be infected, and that if the lacrymal sac were extirpated or the lacrymal puncta cauterized by the galvano-cautery, no germs could enter the conjunctival sac from the nose.

Hirota (*Zentralblatt für Bakteriologie*, 31, Heft 6) carried out similar experiments about the same time. He found that the bacilli of septicæmia and of hen cholera, and the pneumococcus, introduced into the conjunctival sac of the rabbit, only succeeded in infecting it when traumatism was present. He also incidentally demonstrated the influence of the lid action upon the germ contents of the conjunctival sac, by finding that bacteria introduced into the sac all disappeared within ten minutes after the use of irrigating fluids.

In the light of our past experience and of the knowledge gained from the numerous experiments instituted and carried out on animals, it becomes absolutely important that all diseases of the eyelids, edges of the lids, conjunctiva and lacrymal passages, whether suppurative or not, should be treated and cured before undertaking any operation on the eyeball or conjunctiva. Chronic dacryocystitis is the most dangerous source of infection, and if a persistent inflammation of the lacrymal sac resists treatment, the puncta must be obliterated by the actual cautery, or the lacrymal sac must be excised. We have learned by experiments that the bactericidal properties formerly attributed to the natural lacrymal secretion, the tears, do not exist. It is true that successful operations on the eyeball have been performed in the presence of chronic dacryocystitis, but the risk is too great to countenance such unwise action, and the same may be said of operations on the eyeball in the presence of trachoma with purulent discharge. It is by no means safe or wise to be guided in our decision as to operating, by the appearance and secretion of the conjunctiva, even when the mucous membrane is smooth and merely red and swollen, for an inflamed conjunctival sac is never to be trusted. Even after a careful bacteriological examination has been made with negative results, all the steps of an operation should be carried out with the least bruising and violence, in order to avoid preparing a soil in which germs tend to multiply; and we should not operate where avoidable in cases in which unfavorable constitutional conditions exist, as these may indirectly be provocative of pathogenetic germ growth.

All this brings us round again to the ever-present

question: how can the danger of infection be best avoided? From the bacteriological standpoint it would seem that the most favorable results are to be gained by mechanical cleansing of the eyelids and lid-margins and simultaneous irrigation. I do not believe that anything is to be gained by using concentrated antiseptic solutions over indifferent fluids like normal salt or boric acid solutions for purposes of irrigation. Repeated mechanical cleansing with warm water and soap may do for the region surrounding the eyes, the forehead, eyebrows, temple, and cheek, and the external surface and edges of the lids, but the delicate conjunctiva will not bear such rough handling, and is positively injured by the loss of its epithelium, thus leaving openings for the free entrance of germs.

After the forehead, temple, cheek, external lid surfaces, and edges of the lids have been mechanically cleansed in the way mentioned, the conjunctival sac should be repeatedly irrigated with some indifferent sterilized irrigating fluid, and then the fluid collected in the conjunctival sac should be mopped up with sterilized moist cotton pads, before beginning the operation. Operating in this so-called dry manner prevents the entrance of this fluid into the wound, and thus the danger of actually pressing any possibly existing germs into the lips of the wound is avoided.

If care has been taken to avoid operating in the presence of a positively infected conjunctival sac, and if no infection has been introduced during the operation, we may almost with certainty expect a rapid and favorable healing of the wound. The rare occurrence of infection after operation may, perhaps, be explained by the fact that toxic bacteria are not always present, and that when present, they are not met with in great numbers, and consequently their virulence is slight, for the danger of infection increases with the number of bacteria present in the sac, and in contact with the wound. It has been thought by some skilled operators that we have another means at our command for preventing infection after an operation, by doing away with the ordinary protective bandage, and protecting the eye merely by the mask, on the principle that the natural motion of the lids is a valued factor in the normal cleansing of the conjunctival sac. From a bacteriological standpoint this is theoretically correct. But the nature and temperament of the patient must always be considered. In a patient of quiet, equable temperament, it might be entirely safe to close the lids by a strip of adhesive plaster, and protect the eye from external injury by a mask, but in the majority of cases the writer is convinced that the risk of such a procedure would be too great, owing to the restlessness and irresponsibility of the patient.

Summary.—I. A careful microscopical and bacteriological examination should be made of the contents of the conjunctival sac in every suspected case, carrying the examination as far as the cultivation of the bacteria in a proper medium, and the subsequent inoculation of the germs.

II. If toxic germs are found in great numbers, no matter what their varieties, no operation on the eyeball should be undertaken until the germs have disappeared, and the conjunctival sac has been rendered as sterile as we can hope to make it.

III. If there be suppurative disease of the lacrymal passages, whether of canaliculi, sac, or nasal duct, all operations upon the eyeball are positively contraindicated. The lacrymal sac must be excised, and the lacrymal puncta must be obliterated by the galvano-cautery, before any operation on the eyeball is undertaken. In the case of a catarrhal dacryocystitis, or of mucocele of the sac, both canaliculi should be incised, and the sac injected daily with an antiseptic astringent solution, and free irrigation through the nasal duct carried out until all secretion has ceased. Even in cases of great urgency, as, for example, acute inflammatory glaucoma, the writer would not feel himself justified in modifying the above statement.

IV. If the secretion of the conjunctival sac on examination is found to be infected, but the bacteria are few in number and of slight toxic variety, operations may be done on the eyeball when necessary, but these eyes should be opened and examined twice in the twenty-four hours, and the conjunctival sac gently irrigated with warm normal salt solution, or warm sterilized boracic acid solution, and then the eye should be immediately rebandaged.

V. In operating upon the eyeball in the presence of an apparently normal, sterile conjunctival sac, the following steps should be taken:

1st. The forehead, eyebrows, temple, cheek, bridge of the nose, and external surface of the lid should be carefully cleansed with hot water and soap, and dried with aseptic cotton pads.

2d. The margins of the lids should be carefully but gently rubbed with sterilized moist cotton pads, and simultaneously irrigated with a warm sterilized physiological salt solution.

3d. Careful irrigation of the conjunctival sac with the same sterilized normal salt solution, and then closing the lids with a moist sterilized cotton pad. The lids should remain closed in this way until the speculum is introduced.

VI. In all cases the bandage should be removed and the eye examined under the strictest aseptic precautions, as strict as those employed at the time of operation.

VII. On the first sign of infection of the wound, the edges of the lids are to be thoroughly cleansed in the same manner as at the time of operation; the conjunctival sac is to be thoroughly irrigated with the sterilized normal salt solution; the wound is to be reopened and cauterized through its entire length with the galvano-cautery; and the anterior chamber is to be gently but carefully irrigated with a sublimate solution (1–5000); and then the conjunctival sac must be again irrigated, and the lids must be closed simply under a moist sterilized pad.

47 West Thirty-sixth Street

The Causes of Gout.—Falkenstein has claimed that gout is due to a disease of those glands in the fundus of the stomach which are concerned with the excretion of hydrochloric acid, and in consequence of this, exhibit a diminished power. The absence of one of the main factors in digestion causes an insufficient solution of the fibrin in the food and the peptogenic action is inhibited. This leads to the development of foul gases and organic acids. The various urates are not sufficiently broken up, but are absorbed by the blood and deposited in the tissues. Here they remain until solution results as the cause of some other intermediate factor and the irritation produced by their presence in the tissues leads to the inflammatory disturbances recognized as the gouty attacks. As the result of extended experience, Falkenstein has found that gouty individuals can take considerable amounts of hydrochloric acid for prolonged periods with good results as regards the general health and the disappearance of localized deposits. This treatment may be associated with a generous mixed diet, moderate in amount. The only substances contraindicated are sugar, foods rich in nuclein (such as the internal organs of animals), fats, smoked meats, cheese, and eggs.—*Wiener klinische Rundschau.*

THE USE AND ABUSE OF ATHLETICS.

By ROBERT E. COUGHLIN, M.D.,
BROOKLYN, N. Y.

The history of athletics has blended intimately with medicine, and feats of agility and endurance have at all times excited the interest and investigation of capable and reputable physicians, for they are in every sense of the word examples of physiological and functional anomalies. The word athletics was derived from the Greek athletæ which was the designation of persons among the Greeks and Romans who contended for prizes in public games. This was prior to 400 B. C. The system was purely Greek, as were the athletes, although the Romans admired physical skill and strength. No institution exercised a greater influence on molding the national character, and producing that unique type of physical and intellectual beauty which we see reflected in Greek art and literature than the public contests of Greece.

The earliest games of which we have any record are those at the funeral of Patuclus. The belief that the dead would be gratified by the same exhibitions which pleased them in life was a common heritage of the Greeks and Romans from their Aryan progenitors. The competitions were chariot racing, archery, boxing, wrestling, and putting the weight.

In 776 B. C. the Elerians engraved the name of Coræbus as victor in a foot race. This is the earliest record of any contest. Ten months was what all the athletes swore to having taken in preparation for the games at Olympia. Herodicies, who lived 500 B. C., was the founder of medical gymnastics.

The different phases of athletics might be designated as follows:[1] (1) Games and sports that depend wholly or partly on feats of physical strength, such as baseball, cricket, rowing, and swimming. (2) In a restricted sense, feats of strength performed for their own sake, and not as an incident of any game, as throwing the hammer, running, leaping, tumbling, etc., especially outdoor feats in which the maintenance of health is not the prime object. (3) Any system of physical training by gymnastic exercises and outdoor sports.

The physiology of exercise may be epitomized as follows: It increases the action of the heart, causing the blood to flow more freely through the circulation; it increases the rapidity of respiration; dilates the capillaries; increases the activity of the glandular secretions; causes diaphoresis, and incites all the internal organs to act more energetically. It is well to note that exercise calls into play the involuntary as well as the voluntary muscles and that chemical changes are going on in consequence.

Jäger[2] says that gymnastic exercise is most important for the proper development of the muscles and motor power, and ought to be commenced in both sexes at an early age. Systematic muscular activity increases the volume of the muscles and enables them to do more work. The amount of blood is increased with increase in muscular development, while at the same time the bones and ligaments become more resistant. As the circulation is more active in an active muscle, gymnastics favors the circulation. An active muscle also uses more oxygen and produces more carbonic oxide, so that respiration is also excited. The total increase of the metabolism gives rise to the feeling of well-being and vigor, diminishes abnormal irritability, and dispels the tendency to fatigue. The whole body becomes firmer and specifically heavier.

All exercises used in medicine are based on Ling's or the Swedish system, which consists of systematic attempts made to strengthen certain weak muscles, or groups of muscles, whose weakness might lead to the production of deformities. These muscles are exercised systematically by opposing to them resistances, which either must be overcome, or against which the patient must strive by muscular action.

Holmes[3] presents the following as a summary of his paper entitled "The Capacity of Human Muscle for Work": (1) A muscle working under normal physiological conditions is neither "loaded" nor "after-loaded." (2) A muscle will not contract isotonically nor isometrically under normal physiological conditions. (3) When an ergograph is used, a large part of the energy expended by the muscle during a period of work is lost; this loss occurs in easing back the weight or the spring to its position of rest or to the zero point. (4) A recognition of the conditions under which a muscle works and of the end to be attained is necessary when an interpretation of ergographic results is to be made. (5) A normal muscular contraction consists in contraction, relaxation without load, rest. (6) A muscle can work over periods of long duration without fatigue when the conditions are favorable. (7) These experiments confirm the conclusion stated by Maggiora that there is a definite weight with which one can perform the greatest possible work. (8) The physiological limit of a muscle for continuous work is modified by the rate, load, and interval or by rest and work.

Physical Overexertion and Its Effects on Health.—John Knott[4] emphasizes the fact that exercise, in order to do good, must be indulged in with moderation. In analyzing the effects of exercise he says that in an active muscle nutritive changes take place far more rapidly and on a larger scale than in a resting one. The waste products are carried off in larger quantities and new materials are absorbed with greater rapidity. Again, muscle forms so large a proportion of the mass of the body that it is known as the great furnace of the animal economy, about four-fifths of the total heat of the system being involved within it. It is most important to maintain a healthy functional activity of the muscular system. With the increase of the muscular action the amount of waste products is also increased. Up to a certain point the system is able to eliminate this waste, but in overexertion a point is reached beyond which the effete products begin to accumulate in the circulation and in the tissues. Fatigue then becomes manifest.

When the muscular fatigue is carried to excess, the healthy nutrition of the other organs and tissues can no longer be maintained. This condition has a special effect on the nerve centers. When the nutrition of the latter becomes deranged, the nutritional changes and functional capacities of the whole system are disturbed. In the excessive muscular exertion which takes place in running the "brain is overcome by a kind of drunkenness." He believes that the fever of overexertion is due to the poisoning of the nerve centers by the muscular waste products. The heat regulating centers lose their governing powers and the body wastes with slow fever. There are various local affections which are likely to be produced by excessive exercise, such as hypertrophy and dilatation of the heart, aneurysm, and varicose veins. It is necessary for even those who have been blessed with an unusual physique to remember that the overuse of the body may lead to a sudden and permanent breakdown of health.

Violent or prolonged exertion often induces temporary albuminuria. Casts[5] have been found in the urine after a boxing bout when examinations at other times showed nothing abnormal.

Overexertion produces mental fatigue, as many athletes will acknowledge. One instance may be cited in which an individual after a long bicycle ride could not remember his companion's name though

he knew him intimately. This condition is probably the result of an interference in the blood pressure.

Recently there appeared in the obituary column of one of our medical journals the death notices of two physicians who had in their college days excelled in athletics, one at football playing and the other at rowing. The former died of appendicitis and the latter, as the notice read, "of an attack of pneumonia which his weak heart was unable to withstand owing to former hard athletic work in college." Within the past few months the deaths of several noted athletes have been recorded, all occasioned by renal and cardiac disease. One of these was a young woman of twenty-three, who excelled as a swimmer.

A recent writer[6] of an article on "Neurasthenia," in speaking of the etiology of this condition, says: "To the mental training there has also to be added the schoolmaster's craze for athletic development, often carried far beyond the physical strength of the growing boy or girl, and again leading to a depletion of the reserves of energy, which bodes ill for the future capital account of those who, in youth, are compelled to give such hostages to the fortune of their vitality."

In the year 1903 there were thirty-five deaths from football, 500 severe injuries, and sixteen cases of spinal injuries followed by paralysis. Of the 343 fractures, most of them were of the bones of the leg and forearm, ninety-one of the clavicle, nineteen of the femur, and four of the skull. In commenting on these fatalities and injuries, the *Journal of the American Medical Association*[7] says: "The vital question is, does the gain in college pride and college spirit sufficiently outweigh this list of human wreckage?" Dr. Lawrence Johnson has said that a young man in a well-contested rowing race, lasting twenty-five minutes, would use up as much energy as he would actually require ordinarily in a lifetime of eighty years.

An experienced athlete, in a recent conversation with the writer, gave as his opinion that a man sacrifices a certain number of years of his life every time he enters a contest of any kind. He also said that a man when "fit," as expressed by athletes, is in an abnormally nervous condition. In other words, he can never remain at ease for a minute at a time, and like the caged lion is forever on the move during his waking moments. It has been noticed by observers that athletes are often sickly and particularly susceptible to constipation and appendicitis. A case has been related in which a strong man, although sick with phthisis pulmonalis, performed his feats of strength up to a short time preceding his death.

It has been said that the muscles of old athletes are prone to degeneration unless, as is rarely the case, exercise is continued. Cardiac hypertrophy is so commonly found in athletes that the condition has been named "athlete's heart." Like all hypertrophied muscle tissue it is susceptible to degeneration in the same manner as the blacksmith's right arm.

Records kept in gymnasiums show that when a muscle has been hypertrophied by exercise in a short period of time, and the exercise has then been discontinued, the measurement very soon drops back to the original figure. The writer has tried this experiment in two cases with the same result. The changes that go on in the muscle of the pregnant uterus and the tendency of the same toward degeneration when the vital powers of the individual begin to wane are an instance of the great susceptibility of hypertrophied muscle to degenerate.

Valvular murmurs are frequently found in athletes and there can be no doubt that the preceding hypertrophy was an etiological factor in these cases. The writer has in mind at the present time a case in line with the foregoing in which a boy of twelve developed a well-marked murmur after a few weeks' overexertion in riding the wheel.

It is a disputed question whether athletics can cause renal disease. The presence of albumin and casts in the urine upon exertion or overexertion would lead one to believe that renal disease might be the ultimate result, inasmuch as nearly all authorities agree that albuminuria is never physiological. One case occurred in the experience of the writer in which persistent albuminuria was present in a young man of marked athletic tendencies who later developed pulmonary tuberculosis which caused his death after an illness of a few months. In this particular case the family history was negative.

Another case may be cited of a young man who as an amateur sprinter won contests and medals galore. It was a well-known fact that he always fainted as he broke the tape. He is now going through life with a damaged heart as a result of this severe athletic work. Sudden deaths have occurred while wheeling, dancing, wrestling, boxing, running, rowing, lifting heavy weights, and bowling.

It has often been said that many athletes are sexual perverts, and investigation reveals the fact that there are good grounds for such statements. We might explain this condition by stating that severe athletic training and muscle building are at the expense of the nervous and glandular systems.

A few years ago the writer's attention was called to a professional gymnast possessing great strength who was practically impotent. It has been observed by a few that the best athletes possess poorly developed sexual organs. A supposed authority upon matters pertaining to athletics recently made the following satements:[8] "The question of race suicide brings up another point, namely, the effect of severe athletic training upon the sexual power. Physical culture extremists preach that massive masses of muscle are an indication of 'superb manhood.' Facts fail to bear out this theory, the truth of the matter being that severe physical exertion has exactly the opposite effect. This is true, not only in the case of human beings, but also with any animal. It is a well known fact that the surest way to ruin animals for breeding purposes is to compel them to perform hard work.

We need only to look up the records of America's prominent physical culturists and professional athletes, to be convinced of the truth of the above statements. It will be found that comparatively few athletes marry. Of those that do marry, a small percentage have children. A large percentage are divorced by their wives, and it is doubtless true that not a few completely lose the instinct of the normal man."

Benefits of Athletics.—In regard to the benefit derived from athletics one has only to remember the physiology of exercise to become convinced of the fact that exercise *per se* may be very beneficial. The point to bear in mind is to advise the person to stop before fatigue becomes evident. We can do this readily when the athlete is interested in games for the mere exercise, but such advice cannot be offered when his aim is to excel in an athletic contest. Here is where athletics do great harm, and it would be a safe rule to advise against all forms of athletics in the nature of a contest, especially if the person be not in robust health.

Athletics may be said to be beneficial until the heart begins to be markedly hypertrophied; this is the danger signal. A person in such a condition might indulge in light forms of exercise, but should be strongly advised against entering any contest. In

the words of President Roosevelt,[9] "Athletic sports if followed properly are admirable for developing character." Painter[10] says that the elements of noble manhood are a healthy body and a clear intellect. Locke's aim was to give a boy a robust mind in a robust body. "We have overburdened our moral nature," said the Rev. Dr. Percy S. Grant, before the League for Political Education, "We have put too many jobs upon it. Men have to resort to drink, to pleasure, to passion, to relieve their overwrought energies. Good health can do the business, and the direct way to good health is to force young America into camp, gymnasiums, and out-door sports." It would be opportune here to speak of the Japanese as a people among whom athletics have always been popular.[12]

Luther Halsey Gulick[13] calls attention to that class of cases in which the patient is constantly demanding treatment for either real or imagined functional disorders. He says in bicycling alone we do find both the physiologic and psychical conditions adequately met. One of the immediate results of bicycling is a large increase in the respiration. The alternate pressure and relaxation which the diaphragm exerts upon the liver is a factor in promoting the various circulations within that organ. Bicycle riding offers ample diversion and out-of-door air. It provides for exercise of the large muscular masses by a great number of small efforts. It is automatic and so productive of comparatively little fatigue.

Dr. Lucien Howe[14] has said that it is possible to obtain a numerical expression for the general muscular strength of the body. It is also possible to obtain an expression, in terms of a prism, of the strength of the muscles of the eye. The practical application of this knowledge is that, by strengthening the muscles of the body, one could strengthen the muscles of the eye. Dr. E. N. Nash[15] has noted definite and immediate benefit in cases of Bright's disease when patients have played golf as a pastime.

J. W. Dowden[16] says that two factors which greatly conduce to the successful issue of an operation for hernia are the presence of strong abdominal walls and the freedom of these walls from fat. A lax abdomen should be strengthened for a month or more before an operation is undertaken, or if an emergency arise, and an operation has to be performed, exercises ought to be initiated within a week or ten days after the event. The abdomen must be "pulled in" as flat as possible, and this tonic contraction maintained as long as possible. It is astonishing how much can be done in reducing the abdominal girth, especially by the operation of pulling in the abdomen.

Dr. J. Henry Carver[17] claims that faulty metabolism may be restored by proper respiration. In respect to proper respiration and the training of the muscles of respiration, the writer of this paper wishes to state that in his opinion its possibilities in the very young are really remarkable. He has under observation at the present time a child of three years who is able to expand his chest two and one-half inches. These breathing exercises were begun at the age of fourteen months.

Dr. Hermann Weber[18] recently read a paper on "The Prolongation of life" before the Royal College of Physicians (London) in which he said that "regular exercise every day in all weathers, supplemented in many cases by breathing movements, and by walking and climbing tours" are conducive to a long life.

Clifford Allbutt,[19] in a most interesting paper entitled "Rise of Blood Pressure in Later Life," says that "the ordinary man must be warned, as he passes the age of forty, to keep up muscular exercise."

Very full and interesting statistics have been prepared for the *Harvard Graduates' Magazine*[20] by George L. Meylan of Columbia, controverting the prevalent opinion that college oarsmen die young as a result of the excessive strain of boat-racing. Accurate data were obtained concerning all of Harvard crews between 1852, the year of the first race, and 1892. It was learned that of 152 men who had rowed in the university boat during that period, 123 were living on November 1, 1902. Of those who had died, six were killed in the civil war, two had lost their lives by accident, and others by diseases in no way to be ascribed to college athletics. Two died of heart disease, two of apoplexy, one of phthisis pulmonalis, and one of Bright's disease. That is to say, only six owed their death to causes in any manner traceable to the strain of athletic training.

Conclusions:—1. Athletics may be for good or evil and in the same manner as a two-edged sword.

2. The prime object in athletics is improvement of the general health. One writer [21] has said that health, like happiness, does not exist. Each has a goal or limit which, while seemingly attainable, eludes perfect possession. He said the body consists of a number of mechanisms which have the closest and most exact relations, and as they approximate to harmony there is health, but when disordered there is ill health.

3. To obtain good health muscle building is not a necessity. One cannot judge of a person's health by the size and hardness of the muscles. We have seen that the converse may be true.

4. To obtain health one most not be in a perfectly trained condition, owing to the effects of severe training on the nervous system.

5. There is no evidence to prove that athletics and muscle building improve the constitution.

6. One should always keep in mind the fact that built up or hypertrophied muscle has a tendency to degenerate. The heart being a muscular organ shares in this tendency.

7. In regard to the moral side of the question it remains to be proven that athletics *per se* corrupt the morals. Dr. F. R. Sturgis is confident that athletics improve the morals of a community. He has seen cases of masturbation cured by athletics.[22]

8. Although the evidence for and against athletics is contradictory, the whole subject may be summed up by stating that athletics are beneficial when properly and judiciously applied and very injurious when the precautions, above mentioned, are ignored or carelessly regarded.

A CLINICAL STUDY OF CERTAIN FORMS OF PERICARDITIS, WITH REPORT OF A PERICARDIAL EFFUSION COMPLICATING AN EXTENSIVE BURN OF THE CHEST.

By H. EDWIN LEWIS, M.D.,
BURLINGTON, VT.

Pathological conditions of the pericardium are by no means as uncommon as may be inferred from their infrequent ante-mortem recognition. It is true that the symptoms referrable to pericardial involvement are many times completely overshadowed by those of coincident or causal diseases, but with due care and investigation pericardial lesions can be detected in the majority of instances during the lifetime of the patient. Examination of the heart is so often a perfunctory matter and so cursory in its technique, that it is little wonder that little or no information is usually obtained. When pericarditis does occur, however, it is so invariably in connection with certain diseases, notably acute articular rheumatism, pneumonia, pleurisy, and Bright's disease, that the diagnosis of these diseases alone should always prompt more than routine examination of the heart and contiguous structures. In children under fourteen years of age, pericardial involvement should be feared in almost every case of acute articular rheumatism, for it does occur to a certain degree in the great majority of all cases. Likewise in extensive pleurisies in adults, it is rare that the pericardium escapes entirely, though the symptoms may be obscured or ill-defined. The fact is, if pericarditis is looked for, it will be found much more frequently than is commonly supposed, and its occurrence will not be due to the imagination or zealousness of the seekers. Search for any condition with a definite knowledge of what one is seeking for, will prove successful many times, when an aimless investigation will pass unnoticed the most significant signs and prove fruitless. It may be true that pericarditis may exert little or no influence on the ultimate outcome of any disease it complicates, and the therapeutic management of a pleurisy, a pneumonia, or an attack of acute rheumatism may not be changed by the detection of a pericarditis, but there is an infinite amount of satisfaction in knowing all that can possibly be known about a patient's condition, aside from the advantages obviously derived from such knowledge.

There are certain symptoms of pericarditis that occur with a fair degree of constancy, but none of them are subjective. A patient may have pains, precordial distress and tenderness, dyspnœa, dysphagia etc., but these may all be absent even in the presence of the most extensive inflammation of the pericardium The diagnosis must be made from the physical signs alone. The most constant symptom is the so-called friction murmur. In 75 per cent. of all cases of pericarditis an exocardial sound of some character can be heard. I say of some character, for while different writers describe it as grating, squeaking, or rasping, the significant feature is that it is an adventitious sound, usually double—that is, to and fro in its occurrence—and with no definite relation to diastole or systole. It is heard in one place with greatest intensity, and the sound is not transmitted in any direction. Its character or intensity can frequently be modified, or it may be obliterated entirely by having the patient hold a full breath while pressure is made with a stethoscope. Rarely a peculiar sensation or thrill can be felt by pressing with the tips of the fingers between the fourth, fifth, or sixth ribs, one to two inches to the left of the sternum. When practical, and the heart rate can be slightly increased by exercise, the friction sound will grow shorter, and there will be less interval between its back and forth movement. It will be sharper and more clear cut

If the pericarditis goes on to effusion, and it usually does in children from five to fifteen years of age, the friction sounds grow imperceptible or nearly so, and a train of symptoms ensue that make the condition more easily recognized. The area of cardiac dulness increases in all dimensions, but especially in its lateral, and the apex impulse becomes less apparent and soon disappears. In children, bulging of the intercostal spaces soon becomes noticeable and the distension may show itself at the xiphoid angle. Marked dyspnœa and distress is usually evident and the patient complains bitterly of sensations of fulness, in the epigastrium. A peculiar feeling of faintness very similar to that occasioned by palpitation of the heart is frequently described by the patient. The pulse may become feeble and irregular, but it often has an abrupt kick or throb to it every five or six beats. The patient may get very cyanotic, but the face instead of being blue looks red and congested, especially in adults. In this stage pericarditis is usually easily diagnosticated, and careful thorough examination ought never to fail to detect the true condition. The absence or deflection of the heart impulse, markedly increased heart dulness, more particularly laterally, muffled heart sounds, especially at apex, a pronounced dulness to the right of the sternum at the fifth interspace, which varies with change in posture, and a wavy impulse, occasionally felt at the fifth or sixth interspace, make a fairly constant picture of pericarditis with effusion.

The following case is especially interesting because of its etiology and course:

C. B., male, eight years old, had the misfortune to pull a teapot full of boiling tea over on to himself. A severe burn of the left forearm and left chest resulted. The area on the chest was irregularly oval, 6½ to 7 inches wide and 9½ up and down. It was diagonally located, and covered a considerable portion of the left anterior chest wall. The accident occurred about 1 P.M., but I was not called until past 8 o'clock in the evening. The little fellow was suffering severely and had a temperature of 102.4°. I cleaned and dressed his burns, using a soothing ointment, and gave him a hypodermic injection of $\frac{1}{12}$ of a grain of morphine, which controlled his pain nicely. The next morning I saw him and dressed his burns. His temperature was 99.2° and he had little or no pain. For the next five days he got along well, but on the sixth day, about noon, he commenced to vomit and complained of a severe pain in his left side as low as the eighth rib. His respiration was 40 to 44, pulse 128, and temperature 101.5°. The respiratory movement on the left side was much diminished. Physical examination was absolutely negative, but I feared a pneumonia. A twelfth of morphine controlled his pain. I saw him again at 10 P.M. and found him free from pain, but otherwise just about as I had left him at noon, I fancied that there was some dulness behind at the inferior angle of the scapula, but there was no friction sound whatsoever. The heart sounds were normal. The next morning at 9 A.M. there were marked evidences of pleural effusion, and there was

a line of absolute dulness up to the fourth interspace. Respiration was 38, pulse 120, and temperature 100.5°. He had no pain, but his respiration was much embarrassed. The heart sounds were normal. On my next visit, about 2 P.M., I went prepared to aspirate, and finding an increase in the amount of fluid, I tapped him in the seventh interspace in the mid axillary line, and drew off nearly a pint of serous fluid. He received a good deal of relief from the tapping and went to sleep soon after without an opiate. At 9 P.M. the effusion was rapidly filling in again and had reached the fourth rib. The next morning, which was the beginning of the eighth day, I found the little fellow in very bad shape. His respiration was very much labored and his skin was fairly purple. The pulse was 128, regular but abrupt in its character and with its tension much increased. Temperature was only 100.1°. The dulness reached to the third rib and extended nearly two inches to the right of the sternum. There was no apex beat discernible, and the heart sounds were so feeble that they could just be heard. I immediately tapped the pleural cavity again and withdrew more than a pint of fluid. There was considerable relief obtained, but not as much as at the first time. The dulness on the left side cleared up well but the heart sounds still kept muffled and the apical impulse was still absent. Persistence of the dulness to the right of the sternum from the fourth to the sixth interspace left no doubt as to the presence of a pericardial effusion. The burn on the boy's chest was so located that there was no opportunity to do a paracentesis anywhere to the left of the sternum. The indication for the operation, however, was imperative. His respiratory distress was so pitiful and he was so cyanosed that I did not believe he could last many hours without a very great change in his condition. With his parents' consent and a gloomy prognosis, I passed an aspirating needle in at the right of the sternum at the fifth interspace, with an inward and backward direction. Although I pushed it a considerable distance, I did not get any fluid until it passed in over 2½ inches. Then I was able to draw off between six and eight ounces of a cloudy brownish fluid. The relief that followed was one of the most remarkable things I have ever witnessed. The cyanosis cleared at once, his respiration dropped to 26 to 28 and lost its labored character, and in every way he showed that he had been made much more comfortable. I left him shortly after noon, after leaving directions that he was to be given a heaping teaspoonful of Epsom salts in two teaspoonsful of water, every hour until his bowels moved from six to ten times. Shortly after 8 P.M. I saw him again and found him resting comfortably, respiration 30, but fairly good, pulse 104, temperature 100°. His bowels were moving freely, but he was bright and cheerful. There was no dulness above the fifth rib and the apex beat could be plainly seen. The heart sounds were not muffled, but there was a peculiar exocardial sound that I can only describe as a faint sucking noise. It was a single sound and came sometimes at diastole, but more often just after. When the patient took a full breath and pressure was made, the sound disappeared entirely. From now on the boy made a good recovery, and paracentesis of the pericardium or of the pleural cavity was not again necessary. He was kept on syrup of hydriodic acid for over a month, and one year after his heart was normal and free from all evidence of past trouble so far as I could detect. His chest burn took about six weeks to heal perfectly.

I have searched the literature carefully, but I can find no similar case reported in which a burn on the chest was followed by either pleurisy or pericarditis. This case shows, however, that both these complications must be considered as possibilities in chest burns.

Pericarditis as a terminal infection in Bright's disease is of importance clinically only in so far as it hastens an inevitable termination. It is almost always insidious in its onset and course, and often can only be detected at autopsy. The symptoms are more liable to be obscured in Bright's disease by the pulmonary conditions that usually occur late in this malady, but careful examination will many times give strong grounds for suspecting pericardial involvement. Pericarditis when present is often responsible for sudden death in the course of a Bright's disease, and two such cases have occurred in my immediate experience.

In very young children or infants pericardial disease is very apt to assume the plastic form without the development of an effusion. Adhesions follow, and the infant may drag out a miserable existence for several months or a year and finally succumb to inanition. A case of mine that showed extensive pericardial adhesions at autopsy was very interesting to me, for I had excellent opportunity to study it both ante- and post-mortem. A. D., male, aged four months, was a bottle-fed baby that had been a weakly child from birth. For one month previous to the time I first saw it it had had a great deal of diarrhœa. A good share of its food passed through the alimentary canal without the slightest evidence of digestion, although its diet had been carefully regulated by a capable physician of Boston. I saw it at a time when it was particularly bad and was struck by its little old-man face. The baby was fairly quiet, but it gave a little hoarse cry from time to time. It did not cough, but its hoarseness had been noticeable for nearly three months. There was no difficulty in swallowing and the baby was always hungry. The extremities were blue and cold. The rectal temperature was 100, but the pulse was so rapid that I could not count it. The lungs were clear and respiration was about 40. The heart was very much increased in size and there was only one distinct sound. No murmurs could be heard. The abdomen was considerably distended. Treatment really offered little hope, but I was able to help the bowel condition somewhat. Otherwise the condition of the child did not change, though it was able to live a month and several days after my first visit. I was allowed to perform an autopsy and found a tabes mesenterica. The heart was nearly as large as that of a six-year-old child, and was firmly adhered on its under surface to the parietal layer of the pericardium which in turn was completely bound down to the diaphragm. The valves were competent with the exception of the mitral. Where the pericardial surfaces were not adhered there were large numbers of small tubercles. The lungs and other organs in their gross aspects were free from evidences of disease.

I cannot but feel that a good many cases with similar history to the one just cited, would show marked involvement of the pericardium if autopsies were to be performed. I furthermore believe that the majority of all cases of pericarditis occurring during the first five years of child life are tuberculous in their origin, and that tuberculosis is especially liable to attack the pericardium during this period. Every autopsy that I have ever seen of infants dying from inanition or the so-called marasmus justifies this latter conclusion.

In pneumonia pericarditis is a frequent complication, and some authorities go so far as to state that the pericardium seldom escapes in left side pneumonias. I am not prepared to believe this, but I do not doubt that pericarditis occurs far more

often than is generally recognized. That it is a serious complication goes without saying, but it cannot be avoided and calls for little treatment. Its detection is valuable as affecting the general prognosis.

At this point it may be well to speak of the frequent association of pericarditis with endo- and myocardial disease. In acute rheumatism when the pericardium is attacked, the endocardium rarely escapes, and the heart muscle itself may be seriously involved. This fact needs but to be stated to show the paramount need of complete rest in all cardiac lesions complicating acute rheumatism, for we never know how extensive the damage may be, or how extreme the danger.

In conclusion let me say just a word in regard to treatment: The pain of pericarditis can often be relieved promptly by dry cupping or counter irritation over the painful region. Absolute rest in as prone position as possible is a most important regulation. Anti-rheumatics are useless, and nothing approaches the value of Epsom salts in large and often repeated doses, always administered in saturated solution. Heart tonics and stimulants are contraindicated, unless there is evidence of cardiac failure. When effusion takes place and the conditions are not alarming, it is always safe to wait, for it is often remarkable how rapidly improvement may take place by natural processes alone. When the effusion increases to an alarming extent and the patient grows rapidly worse, paracentesis is the thing to do, and the only thing. Carefully done under aseptic precautions, inserting the needle at the point prompted by individual conditions, paracentesis is far less dangerous than to let the patient continue two hours longer in an extremely precarious condition.

51 N. Union Street.

SOCIAL CAUSES OF CRIMINAL ABORTION.*

By INEZ C. PHILBRICK, A.M., M.D.,
LINCOLN, NEB.

That criminal abortion prevails to-day to an alarming degree is patent. For obvious reasons, to arrive at accurate statistics is impossible. The special medical committee appointed by the Michigan Board of Health in 1881, after painstaking inquiry, concluded that one-third of all pregnancies ended in criminal abortion; that at least 100,000 criminal abortions occurred in the United States annually, and that yearly 6,000 women, at the lowest estimate, died from the direct effects thereof.

Not more startling than its prevalence, is the universal indifference, lay and professional, with which it is regarded. In consulting the files of the leading American journal of obstetrics and gynecology for the last decade, I found only three articles upon the subject, this despite the facts that its victims fill our clinics and hospitals; that it is a plague spot upon the fame of the medical profession; that its advertisements contribute a large share to the support of the metropolitan press; that so brazen is its performance that to-day, in the city of Paris, women, making little attempt at concealment, vend its instruments in public thoroughfares; that druggists aid in debauching the public for the profit in abortifacients and catheters; and lastly and chiefly, that it evidences a seriously disordered social state.

All students of the subject to whom I have had access admit its greater frequency among the married, consideration of which class is most germane to the purposes of this discussion. Indeed, resort to criminal abortion by the victims of man's lust and treachery, and their own ignorance and passion, under the stress of threatened dishonor, is by no means of equal significance, as an indication of social degeneracy, to its deliberate and repeated practise in the home.

Our question is at the core neither legal nor medical, nor as a recent medical writer has affirmed, one of moral obliquity, but *social*, and it is only in the light of a scientific study of society, past and present, that its etiology appears, and we gain a foreglimpse of its righteous settlement. An evil so widespread among all classes of people, striking at institutions we deem basic to our civilization, must have roots which spread wide and strike deep. Since time began the dominant biological forces have been economic and reproductive necessity insuring preservation of the individual and the race. This dominance still holds despite the oncoming of an altruism which would place ethical law above physical.

That forms of sex union have ever been determined by economic necessity, that marriage through promiscuity and polygamy to monogamy, has been fashioned according to varying social habit and governmental form, is a fact of scientific demonstration. The institution of the family arose in the dim past out of man's physical and material needs. Its changing constitution mirrors successive stages in his economic history. Large families, prevailingly male, owing to female infanticide, mark the militant phase of primitive existence. In the agricultural, marked discrimination against the female child ceased. To-day, living at the dynamic center of the industrial, the small family is economically (and I think ethically) justified. At first a union for defence, the social and political unit, the family has continuously lost in numbers, power, and cohesion. To-day the individual is the unit; and the State ever assumes more responsibility for the protection, maintenance, and education of the child. Families to-day scatter broadcast. Children, female as well as male, are forced to early enter the industrial field. As a recent brilliant Oriental criticism of our civilization affirms, the family with us rests largely upon a utilitarian basis.

Infanticide, the prototype in the past of present-day feticide, arose out of man's physical necessities. Need of the child primarily, and difficulty in rearing it secondarily, determined for or against its leave to live. Simplest habits among primitive peoples obviated the need of many household workers. Fighting men constituted the supreme need. All superfluous members of the family or clan were a serious handicap. Hence arose female infanticide. In the usefulness of woman in the varied industries of the agricultural stage the female child won recognition of its right to live.

To-day, in the midst of the stupendous material achievement with which scientific invention has invested our civilization, contemplating the ever vaster reaches to which the human mind is attaining in the presence of working forces of moral and spiritual uplift which are distinctively the product of our civilization, we yet maintain a standard of sex relationship consistent only with barbarism. We make merchandise of the bodies and souls of a half million of our women. Venereal diseases in a majority of the adult male population (for the prevalence of gonorrhœa is placed by competent authority at 80 per cent.) exact tribute in health and happiness of themselves, their wives, and, in the case of syphilis, of their children and unborn generations. A million defectives cry out against the crime of unfit marriage. Economic necessity not making necessary the determination of the sex of the child before its taking off, we substitute feticide for in-

*Given as part of a symposium on criminal abortion before the Nebraska State Medical Society, May 5, 1904.

fanticide, and kill it in its mother's womb. The cause of all this is the reaction of the stress of modern industrial conditions upon an inordinate sex instinct developed out of all proportion to its legitimate function, reproduction of the race.

Chiefly responsible for bringing about this enormous exaggeration of the sex instinct must be indicted the economic dependence of women throughout all the past upon the exercise of her sex function. It is a biological law that in the process of time, the living organism becomes adapted to its environment. Man has been woman's environment, her source of food supply, as a brilliant writer upon this subject puts it. All she had, all she could get, came through her sex relation to him. Inevitably sexual characteristics developed to the suppression of human faculties, which were her heritage as well as his, and which only in very recent times have received expression and exercise. It is no wonder that woman, segregated to the exercise of the sex function, became a creature whom an eminent deceased gynecologist some years ago dared characterize before a large class of men medical students as constituted of sexual—and, incidentally, other organs, or that she had given birth to a race of libertines. By this sexuo-economic perversion man, directly and by inheritance, as well as woman, has been sadly handicapped in his progress toward higher living.

I maintain that criminal abortion arises from a perverted sex relationship brought under the stress of economic necessity. Subsidiary to this are disturbed marital relations with consequent weakening of family ties. Dr. J. W. Taylor, professor of gynecology at Birmingham University, in a recent article in the *British Medical Journal*, after indicting the practice of criminal abortion as chiefly responsible for the diminishing birth rate of Great Britain, affirms the latter ultimately due to causes operating in the married life of its inhabitants, to debased ideals therein obtaining. That here, as there and everywhere, something is seriously wrong is indicated by the alarming frequency and increase of divorce (greater in the United States than all the rest of the civilized world).

The assertion that discontent with marriage as evidenced in divorce is but a parallel manifestation to discontent with life shown in increased suicide, and that with modern trade relations in increasingly prevalent strikes and lock-outs, that, in short, it is but one of the inevitable accompaniments of a time of social upheaval, is doubtless true; but there are, besides, specific factors at work. Foremost among these is revolt against that debased idea of marriage, revealed in an institution nothing better than enforced prostitution and slavery, which characterized the primitive stages of human existence, and from the ever shortening shadow of which we have not yet emerged. Economic freedom is opening to woman escape from the degradation of such marriage. False ideas disseminated by fiction and drama, evoking happiness and good out of impossible unions, teaching, as one medical writer puts it, bad philosophy and bad morals in that any alchemy could change the dross of such marriages into gold, inevitably tend to disastrous matrimonial failures.

Sociologists recognize and affirm that the family is in a state of reconstruction, that the old form is proving insufficient to meet new conditions. Readjustment of social relations is ever painful. Into the chaotic organization of the family at present so largely obtaining, it is not to be expected that children will be welcomed. The problem of family relations is complex enough without the introduction of complicating factors. Limitation of the number of offspring by legitimate means, marital continence, will be the exception, and resort to criminal abortion the rule.

It must be conceded that occasionally criminal abortion is the resort of persons of intelligence and, for the most part, high ethical motive, it being deemed by them a lesser evil than bringing into the world children inadequately outfitted in constitution or opportunity for the journey of life. Such inconsistence bespeaks either domination of husband and wife by a lower, while recognizing a higher, law, or a lack of accord between them regarding marital indulgence, and the acceptance of its legitimate consequence. My professional experience confirms the belief that the latter condition not infrequently obtains; and that the husband is oftenest the aggressor both in indulgence and insistence upon criminal abortion. Certainly a majority of the married women who have requested an abortion at my hands have given as a reason their husband's insistence. I can conceive no lower depths of selfishness and brutality to which humanity can descend than is revealed in such a statement.

Responsibility to children on the part of parents and the State is felt as never before. Laws of inheritance are ever better understood. The tide of ethical and intelligent sentiment is turning toward the small family, one commensurate with the well-being of parents and their ability properly to maintain and educate. Remembering, as Ida Husted Harper affirms in an able recent article in the *Independent* on the "Small vs. the Large Family," that there are now thousands of children for whom there are no school privileges, more workers, than work, and well-nigh a million defectives filling our hospitals and charitable institutions; that according to the estimate of Gihon, there are 2,000,000 active syphilities in the country, and that the number of chronic alcoholics is far greater, it is plainly time we are shifting the emphasis from reproduction to becoming worthy to be reproduced. It should not be extolled, nor even admitted ethical, for a woman to bear a large family if it entails sacrifice of the precious heritage of *living*, most certainly not if children be ill-born or handicapped in opportunity; nor for a man to spend his years in drudgery denying every higher need for their half-maintenance. Limitation of the number of offspring is often a duty, but feticide is *not* its ethical method. Marital, as well as social continence, is a crying need of the hour. Nature, unassisted by man, will in the process of time effect this limitation; but for the diseased and degenerate, it will be through the tragedy of survival of the fittest. Nervous energy expended in intellectual and moral activities will lessen the number while improving the kind of offspring. That on the lower planes of living, intellectually and ethically, reproduction will be out of all proportion to ability to rightly maintain children goes without saying Upon the well-born and well-reared, with the added means and leisure that smaller families insure, will fall the burden of care of these unwelcome, unprovided, and often defective wards of society.

To-day in America we exhibit the ultra-materialism of a material age. Home, church, and state are commercialized. As truthfully said in a recent epoch-making book, "The children of the spirit have slipped through the iron net of our destinies, but the children of the world we have gathered into our granaries." However we may idealize, the final test by which to-day all is tried is the economic one. Does it pay to rear children? is the question which negatives parenthood in many homes; and economically speaking, the answer is justified.

Given excessive production, with ever greater congestion of population in cities, these entailing high cost of living; this further increased by control of the necessaries of life by trusts; with the need of industrial workers enormously reduced by labor-saving machines; in the midst of false standards of living set by the very rich, toward which, with a mistaken notion of the prerogatives of democracy, *all* aspire, the rearing of children, economically considered, is a matter of serious moment. Until there shall be readjustment of industrial conditions, with return to the soil of a large portion of the urban population, and a standard of plain living and high thinking replace its opposite, we cannot expect to eradicate the evil under discussion, nor many of its concomitants.

That entrance of married women into the trades and professions is not a considerable factor in the preponderant resort to criminal abortion by married women, has abundant proof. The number of married women as compared with single engaged in industrial work is insignificant. The report of the Illinois Bureau of Labor Statistics, 1892, shows that of women employed in Chicago in all industries, including manufactures, department stores, hotels and the telephone service, 95 per cent. were single, 3 per cent. widowed, and 2 per cent. married. The Fourth Annual Labor Report states that nineteen-twentieths of the working women investigated were either widowed or unmarried. In twenty-one leading American cities there were 15,387 single women, 1,038 widowed, and 745 married. The Chief of the Michigan Labor Bureau reports 90 per cent. single out of 13,139 female workers. In England, where in certain towns a very large proportion ($\frac{1}{4}$ to $\frac{1}{3}$) of married women work in textile factories, it is not reduction in birth rate through criminal abortion that is so alarming (they have not the price), but the frightful infant-mortality which prevails, for example, Manchester and Preston in 1891 showing a mortality of 220 to the 1,000.

Investigation does not warrant the statement frequently made, upon which much stress is laid by certain writers, that among single women entrance into the trades and professions tends to increase illicit sex relations, and thereby criminal abortion.

On the contrary, careful investigation establishes the higher than average morality of working girls and women. The Seventh Biennial Report of the Bureau of Labor Statistics of Illinois, 1902, says, "There is clearly small occasion for apprehension concerning the moral influence of industrial employment upon young women as a class, when 95 per cent. of them are securely sheltered within the home circle and when 75 per cent. of them are assisting their parents and thus giving daily outward expression of the cardinal virtue, filial piety." Commissioner Tobin of California, quoted by Prof. Helen Campbell in her "Women Wage Earners," states that working women and girls, as a whole, are found to be hard-working, honest, and moral members of the community. Investigation by the Massachusetts Bureau of Labor Statistics in fourteen cities demonstrated the high moral standing of working women, and the fact that a very small proportion of working girls recruit houses of prostitution, and that this small percentage is drawn largely from girls employed in domestic service or the notoriously underpaid industries, shirt and coat making and the like. This latter statement is verified for England by Mrs. Amie Hicks, President of the Rope-makers Union of England, in her testimony before the International Council of Women.

That among the young and ignorant and the victims of inherited tendencies, many will offend against the law of chastity, goes without saying. And until a righteous public sentiment shall aid the unfortunate girl to rehabilitate herself as a respected member of society, criminal abortion will be the resort of this class. And we cannot blame them. Positive morality has ever been born of contact with and resistance to evil. Out of woman's increased contact with the world will in time arise a more intelligent, honest, and courageous womanhood, divested of that pettiness of mind and heart entailed by her long segregation in the home to the exercise of sex and primitive industrial functions.

Of institutional and personal influences which must be enlisted if we would successfully oppose this evil, chief are those of the press, the church, and the medical profession. A generation is still with us that knew the American press in the day of its greatness, its dignified and ardent championship of moral issues, when through its columns leaders forged a path direct to the heart of the masses. To-day we may well bow in humiliation at the transformation fifty years has brought—a press which is either a capitalistic enterprise or the register of a party machine; whose editorials are made, not felt, to meet the exigencies of financial control; the bulk of its matter pandering to the lowest taste of its constituency; its expense largely borne by a mass of advertisements of doubtful character or positive immorality.

It needs no argument to prove that the church in the ecclesiastical sense, that of an institution endowed with disciplinary authority over the acts and beliefs of its adherents, has well-nigh passed, the Catholic alone, amongst Christian churches, claiming and exercising, to any considerable extent, such prerogatives. At the best, the church stands before the community for moral uplift and organized service; at the worst, an aid to business, an impetus to social preferment, a cloak to cover a multitude of sins. Modern science in a century has overthrown the foundations of past theologies; but unfortunately gain in ethics has not been proportionate to the lopping off of superstitions. In the interregnum, till men shall have replaced the outer authority of the church they no longer recognize by an inner ethic sense, society will miss the fear o' hell, the whip "to haud the wretch in order." That the Catholic Church does exert a considerable deterrent influence on the practice of criminal abortion is admitted. If the Christian Ministry would justify its continuance, let it bring to the people the gospel of clean living and fling aside the dry husks of doctrine devoid of soul-sustenance. Let it order well its life. The example, unhappily too frequent to be exceptional, of a minister of "the earth, earthy," the husband of a pale, worn mother of many living children, or of as many destroyed in utero, will efface from the memory much godly precept. Mayhap the true minister to his people will be asked to seek another field of service, but he will have left behind the mite of leaven in the lump.

When all is said, it remains true that chief responsibility for the prevalence of criminal abortion rests upon the medical profession. It is a matter of common knowledge that in every community members of the profession live by its induction. Not infrequently one learns of those in high places who have their price. But far greater than sins of commission are those of omission. That the profession has failed to assume the responsibility of speaking in certain tones and with an authority founded upon supposed fitness of training and adequacy of knowledge on the vital questions of sex which vex our civilization is, in the light of its history, explicable. Traditions long surrounding medical schools were

not those exalting chastity. Not infrequently professors counselled students to libertinism rather than virtue, and lent the force of example to that of precept. The name of medical student was a synonym for license. With higher requirements for entrance to the profession, and co-education, moral standards have risen. No more striking proof of this is needed than the medical declaration concerning chastity published in the *Philanthropist* some years ago, and signed by sixty-seven of New York's leading men practitioners. For sins of commission an over-crowded profession containing a large percentage of the unfit, intellectually and ethically, is responsible. With poverty confronting not alone the physician, but his helpless wife and children, we cannot expect that he will be scrupulous in his choice of work. Certainly many men and women would be deterred from the commission of abortion by instruction from their medical attendant regarding the dangers involved to the mother, and an understanding that the distinction between the quick and the non-quick fœtus held by the ancients, and handed down to us in English Common Law, is purely arbitrary and unfounded. That this distinction dominates the thought of the ignorant is known to all of us; and it is a matter of personal knowledge that sometimes for this mistaken notion the physician is responsible. Few abortions, even among the illegitimately pregnant, where there is every incentive, are induced after quickening, a fact for which the greater difficulty in induction does not account.

The practice of medicine enjoins much knowledge that is not technical, and much prescribing that is not of drugs. It implies investigation and understanding of the hidden social sources of disease.

THE GENESIS OF SLEEP.

By AXEL EMIL GIBSON, M.D.,
LOS ANGELES, CAL.

"How wonderful is Sleep" once said that British child-poet Shelley—"Sleep and his brother Death." Like death, sleep is shrouded in mystery, and presents the same difficulties of examination—difficulties which have their basis in the failure of the subject to observe itself as the object; the self-conscious man to identify himself with the subconscious man. As he enters the strange sphere of this inner life, he obliterates his tracks by abandoning himself to the guidance and protection of an undefinable, and so far, entirely uncontrollable conveyance. The fearlessness and complacency with which he surrenders his personal identity to unknown agencies would remain wholly inexplicable were it not for the presence of a constitutionally resistless necessity which subdues any feeling of fear and uncertainty.

The great questions which the sphinx of sleep holds up before us refer especially to the necessity, the cause and determining conditions of sleep. Perhaps the personal experience of a great majority of men has already satisfactorily answered the first of these questions. Sleep, at least in the present stage of evolution, seems even more necessary for the maintenance of life than food itself. Thus Dr. Marie de Manassein of St. Petersburg, in numerous experiments in this field of research, has found that puppies, while capable of sustaining life, even after a twenty days fast, break hopelessly down after an absence from sleep of only five days.

In the progress of these experiments the bodily temperature of the sleepless puppies went down rapidly, followed by a decrease in the number of red blood corpuscles and an arrest of leucocytes in the lymphatic channels. As the experiments drew to a close the amount of hæmoglobin increased, followed by a thickening of the blood mass, the latter fact perhaps being due to the refusal of the animals at this stage to accept food in either liquid or solid form, while the kidneys still continued to functionate. *Pari passu* with the fall of body temperature, the general reflex movements assumed the character of a marked periodicity, manifesting alternately in the opposite sides of the body, and thereby demonstrating the possibility of the two cerebral hemispheres, during certain conditions, to act in turn. Thus it was noticed that the pupils of the eyes reacted with alternating power to external stimuli. While from the very beginning a serious derangement of nutritive processes was observed, the main effect from the want of sleep appeared in a series of pathological changes in the centers of celebral cortex.

In their experiment on human subjects where subjective experiences shed new light on the field of research, Prof. R. Patric and Dr. J. A. Gilbert of the Psychological Laboratory of the University of Iowa, ascertained that there is an exception to the rule of a general weakening of functional reflex actions. Thus it was found that vision in place of weakening through an enforced sleeplessness, actually increased in acuteness. On the other hand, memory and the power of attention suffered greatly, and one subject, "after eighty hours of sleeplessness, found it impossible to commit to memory in twenty minutes what normally required two minutes." These formidable inroads in the field of the "psychic centers" were furthermore evidenced by uranalysis, which showed an enormous increase in the output of phosphoric acid.

Another fatal change in metabolism, resulting from absence of sleep, lies in the failure of the blood to "fix" oxygen. The gaseous exchange in metabolism being thus impeded, the support of the cell-structures requires a compensatory increase of hæmoglobin—a fact which explains the strange acceleration of the blood-stream so universally observed in persons subject to sleeplessness.

The necessity of sleep has thus a basis in the rest required by the system for the repair of broken-down tissue and subsequent reëstablishment of a disturbed equilibrium. The real problem in sleep, however, does not so much concern its necessity, as the *part of our nature which is subject to this necessity.* By repeated experiments the fact seems to be established that sleep only in a very slight degree interferes with the functional activities of sympathetic life. The abdominal reflexes remain constant, and the respiratory movements increase in depth and become more rhythmical. Some physiological processes, as, for instance, the action of the sudoriferous glands, become in sleep even more energetic than in waking—owing perhaps to the fact of an increased blood-pressure in the peripheral vessels, resulting from a lessened demand for blood in the brain and digestive apparatus. And as the sudoriferous center is located in the medulla oblongata, it logically follows that the vital processes unfolding in this center, in place of relaxing during sleep, have actually increased in vigor.

Most investigators of the phenomena of sleep have agreed to find its immediate cause in cerebral anæmia. Perhaps, however, it is largely due to the genius of the famous physiologist Hilton, that cerebral anæmia as the cause of sleep, from being a mere theory has attained a scientifically demonstrable basis. One feature of his experiments consisted in compressing the jugulars, and from the circulatory changes ensuing obtain a means to determine that cerebral anæmia is due, not to venous stasis, as had

been supposed, but to the spontaneous contraction of the arterioles, *i.e.* to vasomotor action.

So far sogood. The next step was to find the cause prompting the vasomotors to their unwonted action. Girondeau of Sorbonne offered as explanation the theory that the lymphatic spaces around the cerebral vessels, being filled with lymph during sleep, exerted a pressor effect on the blood stream and thereby retarded the circulation. On the other hand Professor Pflüger of Berlin believed that in the special action of carbon dioxide (CO_2) on the blood and tissues, a strong cause was found for sleep. Having ascertained that cellular activity ceases the moment oxygen is used up and replaced by carbonic acid, he associated this fact with the phenomenon of sleep. For as the brain requires an enormous vital energy to sustain mental action, and this energy is generated by the series of violent oscillations or explosions caused by the formation of CO_2 through the action of oxygen, it would follow that the exhaustion of oxygen would asphyxiate the brain, bring consciousness to a stop, and thus cause sleep.

Lately Dr. Howell has published a theory which holds that the immediate cause of normal sleep lies "in a vascular dilatation in the skin, causing a fall of blood-pressure in the arteries at the base of the brain and thereby producing an anæmic condition in the cortex cerebri."

A still more recent view has been advanced by Prof. Leo Ferrare of Brussels, who regards sleep as essentially a process of physiological intoxication. He bases his theory on the ascertained presence in the blood of poisonous alkaloids, generated in the breakdown of tissues in the tired body. When in the course of time these alkaloids have increased to a degree exceeding the checking influence of oxygenation, they are retained in the cerebral tissues where their narcotic action at length produce fatigue and sleep.

Professor Ferrare's view, with more or less modification, is the one mainly supported by subsequent investigations. It assists to a greater extent than any other theory in the admirable working out of a large number of otherwise inexplicable phenomena. Through it we are in a position to look upon action, fatigue, sleep, reparation, equilibrium, and awakening, not merely as chronologically successive events, but as phenomena chained together in a cycle of causative order.

And. as in a thunderstorm, the very intensity of the elementary discharges generates a new energy, the action of which is to neutralize the generating cause itself and thereby bring the storm to a close, so in the cellular activities of the waking man are formed catabolic products whose toxic influences on the vasomotor system introduce chemical and mechanical changes of the blood, leading to fatigue and sleep.

These researches, however valuable in themselves, do not strike at the very heart and center of the problem. We are not informed what sleep is *per se*, but only what are the metabolic changes which lead up to, and culminate in, the phenomena of sleep. We have ascertained that the physiological reflexes under the control of the medulla oblongata remain largely intact, while the functions belonging to the volitional group, with their controlling center located in the cerebral cortex, are held suspended during sleep. Hence it may be stated that sleep is a cerebral, rather than a spinal-sympathetic process. All investigators, from Hammond with his watch-glass inserted to cover the exposed brain in the trepanned skull of a dog, to Professor Torcheneff with his experiments by electrical stimulation of the cerebral cortex of his sleeping human subjects, have agreed that cerebral anæmia is coincident with sleep, while the medulla retains its supply of blood undiminished. And as the medulla stands to the involuntary or sympathetic life of the body in the same relation as the cerebral cortex to the volitional or cerebrospinal, there is certainly a strong reason for connecting the necessity of sleep with the position in which the two systems stand to each other.

In the life-history of this planet the sympathetic consciousness precedes the cerebrospinal. The purely vegetative life, after having reached a certain degree of individual survival-value, required a devising agency as protection against alien environments. The supply, which in the history of life always follows upon true evolutionary demands, took form in the unfoldment of the cerebrospinal system. Henceforth while it remained the function of the medulla to sustain and keep in repair the evolutionary vehicle, it became the function of cerebral cortex to direct its progress.

At its first emergence, a mere overshadowing, hardly perceptible impulse, this directing center gradually fixed itself in the animal consciousness and proceeded to evolve centers of motor control. Having firmly established itself in the cerebrum, this new evolutionary factor expanded its dominion into the very center of the organism in the form of the magnificent spinal column. By a series of equilateral and equidistant projecting fivers, this column provided an agency under cerebral control of peripheral motor functions, using the corresponding organs as a means of locomotion, protection, and support. Even to internal functions, this powerful system has extended its controlling influence, as is witnessed in the workings of the lungs which half the time yield to the cerebral consciousness. Likewise the movements of the heart and intestine in exceptional cases have been found susceptible to volitional efforts. And, as in every effort of nature is contained a prophecy, it is evident that the course of natural evolution aims at a gradual, but complete conquest of the sympathetic system—the impulses of the senses to be subdued by the master-touch of *will*.

Now in this unceasing pressure of the cerebral consciousness on the sympathetic we find the cause of the phenomenon of sleep. Its necessity springs from the friction, the wear and tear resulting from the expense of one power at the expense of the other. *Volitional* life advancing on *instinctual* life, the life of *culture* imposed upon the life of *nature*, cause a break in the rhythm of vegetative existence, and the ensuing rupture of physiological balance finds in sleep a condition for the reëstablishment of a disturbed equilibrium.

For the sympathetic life may in this connection not unfitly be compared with the expanse of a shoreless ocean in which the cerebral consciousness constitutes the advanced jetties preparatory for the upbuilding of permanent structures. The rhythmic waves of vital energies, manifesting in the sympathetic life, batter the foundations of the cerebral mind-structures as the latter fashion themselves into a new order of existence with its good or bad habits of life; its indulgences, tendencies, violations; its constructive or destructive modes of operations.

The effort of this new consciousness to actuate its impulses through the sympathetic agency has a direct bearing on the physiology of the structures involved. The lines of pressure are strewn by cellular wrecks, disturbances which in a short time would result in a general destruction of the organism were it not for the

subtle metabolic mechanism, brought into operation by the very output of the destructive process itself, *i.e.* the toxic substances generated in the ruptured cell-structures. These toxic substances impinge on the vasomotors, which under the stimulus of this irritation assert their constrictive qualities and close up the cerebral vessels. The anæmia which thus ensues unfits the cerebral cortex to functionate as a vehicle of self-consciousness, and hence give rise to the suspension or cerebral activities known as sleep. This suspension lasts just as long as is required for the sympathetic system to neutralize and remove the toxic substances from the involved tissues and to repair the broken-down cell-structures.

This view is borne out by the fact that the lower animals whose cerebrospinal system is yet too undeveloped to offer any telling resistance to the sympathetic life-current, do not require sleep. Fick and Neumann, well known in the world of science, have dealt exhaustively with this subject, and come to the conclusion that to the animal sleep is the less necessary the more the sympathetic system with its reflex movements predominates over the brain with its voluntary movement. The same indifference to sleep is recognized in an animal part of whose brain has been removed. Thus Goltz, by experiments with his famous brainless dog, and Stephani with his pigeons, have collected evidences that seem to establish the fact that the necessity for what we term sleep has its basis and determining conditions in the struggle of the cerebral consciousness to extend its dominion in the sympathetic life—a struggle which ultimately must result in physiological fatigue of the cerebral structures, with the subsequent departure of self-consciousness.

Hence it is self-consciousness—that endless sliding scale of intelligence, running through the progressive stages of an advanced evolution and furnishing a register for the power of individual self-analysis and self-realization—it is self-consciousness in its strenuous efforts to extend its dominion and intensify its power of vital control, that causes a weakening of the tenacity of the cell-structures which form its physiological center, and hence brings about the necessity of sleep with its rest and repair.

Considered *per se*, as an integral energy, the cerebral consciousness, by virtue of its power to evolve self-consciousness, transcends by far the consciousness of the sympathetic. And as the latter has been demonstrated to carry on its regenerative work in defiance of sleep, it would be illogical to accredit the cerebral consciousness with wielding a less degree of self-generating energy. Hence it is not in consciousness as such we shall search for the necessity of sleep, but in the cerebral vehicle which furnishes the machinery for its operations. Consequently any fixed, monotonous attention tires and exhausts. The stress of insomnia which an individual may experience after an intense and protracted attention, only apparently contradicts this fact. For when self-consciousness, in pursuit of some fascinating goal, becomes heedless of the warning signals sent up by the sympathetic center, the strain may result in a partial disconnection between the cerebral and the systemic circulations—a condition which means that the blood-currents in the cerebral arterioles under the overplus of volitional stimuli have overcome the natural checking influence of the vasomotor constrictors. A stream of blood is thus surging about the cerebral vessels, continually adding new fuel to the flames of a high-wrought imagery. The medulla has lost its grip on the cerebral engine, and the latter, if not counterpoised, may end its mad career in the ditch of mental aberration.

And as thus mental overwork or too strenuous attention may give rise to insomnia, so mental inertia or lack of attention opens the mind to the influence of sleep. In the one case, however, there is fatigue without sleep, and in the other, sleep without fatigue. Yet the incongruity in these relations are merely apparent, as the inattentive or weak mind, having no firm hold on the cerebral dynamo, is readily dislodged by the waves of vegetative life rolling in over the sympathetic conduits.

But to the normally active mind, fatigue and sleep follow upon protracted attention. This, however, does not mean that the individual should resistlessly yield to the first impulse of sleep. For the brain cells must be trained to endurance and resistive power in their struggle for cerebral independence. And by virtue of the power of concentration, innate to most individuals, the mind is capable of forcing the instrument to yield a moderate amount of work in excess of its normal limits.

From this it naturally follows that the necessity and length of sleep depends on the strength and intelligence of the consciousness engaged. The firmer the hold, which the self-conscious *ego* through the action of the mind exerts over its brain-vehicle, by conforming to the laws and principles governing the sympathetic life, the less friction ensues, the less time is needed for repair, and consequently the need is less of the condition called sleep. Hence the power of some strong minds to exist normally on a very small amount of sleep.

For there is an unmistakable tendency in the course of a higher evolution—the evolution of the will—to encroach upon the domain of sleep. Men of towering intellect and singularly pronounced individuality, during all times and ages, have been able to sustain their life with a measure of sleep which to ordinary men would have meant physical and mental breakdown. Thus in Dr. Binn's book on the "Anatomy of Sleep" we find a long line of epochal minds who were able to sustain a gigantic mental activity on an incredibly small amount of sleep. The sleep indulged in by Lord Coke, Sir William Jones, Bismarck, Gladstone, Zola, seldom exceeded the limit of six hours, while Wesley, Goethe, Schiller, Napoleon, Balsac, Humboldt, Mirebeau, mostly contented themselves with four or five hours of sleep out of twenty-four. Jeremy Taylor, Baxter, and Bacon, we are told by the same authority, seldom allowed more than three hours of sleep a day.

The fact, already referred to, of the absence of ordinary sleep in animals of slightly developed or non-developed cerebrospinal system, and in animals whose brains have been partly removed, does in no way contradict the other fact just mentioned of the power of a highly-developed cerebral consciousness to approach a similar independence in relation to sleep. For while in the former case the unhampered sway of the sympathetic system precludes friction, and thus renders the restorative and readjusting phase of sleep unnecessary, on the other hand the development and ascendency of the cerebral consciousness into a controlling and self-adjusting power also preclude friction, by overcoming it. The central fact by and through which the whole complexity of sleep receives its logical meaning and explanation is found in the presence of an untiring self-consciousness, which in its manifestation through the cerebral cortex in terms of a feeling, sensing, perceiving entity, causes friction in the cell structures of its limiting vehicle—a friction which gradually, through the irritation of the vasoconstrictor center, leads to cerebral anæmia and sleep.

Nature's motto for mental growth is spelled *attention*. The inattentive and sluggish mind is always sleepy. At odd intervals the tired-out or inattentive

individual will find strange symptoms assert themselves in his functional mechanism. A series of pharyngeal and respiratory movements start with a deep irrepressible inspiration; the mouth is thrown wide open and the glottis is contracted, and this is followed by an energetic, almost convulsive stretching of the body and limbs. This movement constitutes what is termed yawning.

The phenomenon of yawning lends scientific strength to the view of sleep here taken. It graphically demonstrates the character of the subconscious conflict going on between the two nervous systems. The individual yawns when bored, *i.e.* when inattentive. The self-conscious *ego*, if working through a weak mind and in absence of external stimuli, will gradually lose its grip on its sense-functions, which thus glide into a condition of inertia. For a moment the volitional phase of respiration is on the verge of arrest, when the medulla, informed per vasomotor connections of a threatening asphyxia through the retention of carbon-dioxide in the hæmoglobin, saves the situation by assuming entire control of the respiratory function, and with a deep energetic breath inflates the lungs. The imprisoned carbon thus liberated by the sudden inrush of oxygen gives rise to a series of cellular explosions which may attune the retiring mind into a new rapport with its sense organs, and thereby cause the half-sleeping individual to wake up with a start. Should, however, external conditions be favorable for permanent repose, the relief of the cerebral consciousness from the function of breathing, may end in the entire surrender of its functional domain to the sympathetic consciousness. And this is sleep.

Another not less graphic illustration of the rationale of sleep lies in the involuntary closure of the eyelids of the sleepy person. The mechanism involved in this phenomena is initiated by the relaxation of the motor oculi, with the subsequent release of the orbicularis palpibrarum which thus close the moment the volitional center in the cortex, through cerebral fatigue and anæmia, is unable to transmit the corresponding motor impulse. And as the orbicularis palpebrarum, like every other sphincter muscle, is suspended between the action of two opposing sets of nerves, the voluntary cerebral and the involuntary sympathetic, it follows that the inhibition of the former will turn the power of balance over to the sympathetic center, and thus result in the dropping of the eyelids.

Hence we find sleep corresponding to the removal of self-consciousness from its cerebral vehicle. This shifting of consciousness insures rest and recuperation to the set of functions connected with its normal activity, leaving the medulla in undisputed control and responsibility of the entire sensuous apparatus. Quietly, harmoniously, this powerful, though subconscious nerve center leads the life-current over the unobstructed nerve circuits, removing broken-down cell rubbish, replacing old structures, and healing and upbuilding the disordered elements of the body.

"The medulla," says Dr. Leonard Hill in his book on "Cerebral Circulation," "is the hub around which turns the wheel of a man's vital functions." Like an unsleeping sentinel the medulla posts at the threshold of the vegetative life, maintaining through constant adjustments the orderly course of functional activities. It holds the keyboard to the network of nerve-threads, along which waves of messages sweep up and down, from and to the sensory relay-stations and subcenters of the body. Situated at the upper end of the spinal column, the medulla guards the entrance to the higher "psychic centers" during sleep. To the relations occupied by the medulla to these centers, the scientists of all lands have lately paid the keenest attention. With a mathematical nicety, precluding any possibility of error, the famous Italian savant Dr. Masso, by the aid of his ingenuous plethysmograph, has recorded the variations which take place in the volume of the brain during the condition known as sleep. He found that "while its size diminished during sleep, every sudden noise or light disturbed its repose, causing an instantaneous increase in its volume, yet without the awaking of the sleeper." The vibratory waves of sensation rolling in from the exposed senses were interceded by the medulla, the faithful watcher of the subconscious life, adjusted and silenced.

Thus the connection between the cerebral consciousness and the general sensorium, though suspended during sleep, is still intact. At any moment the medulla is capable of reaching the retired mind. Hence a pain the intensity of which may indicate a deeper change in the physiological situation and therefore requiring the attention of self-consciousness is instantaneously translated into terms of vasomotor movements, resulting in the loosening of the constrictors with the subsequent effect of flushing the cerebral centers with blood—and the thereby induced self-consciousness returns to the field of action. Again, if the sensation be only of a trifling character, as in the form of a light sound or surface touch, the stimulus is too weak to impress the medulla with any sense of danger, and is therefore only faintly reechoed in the mind, where it yet may form material for dreams. Thus dramatized into events, such stimuli largely furnish the *dramatis personæ* on the stage of our ordinary dreams.

In this dream life we find irrefragable evidence of the continuation of self-conscious existence beyond the border of ordinary waking consciousness. The dreamer has at his disposal a full set of sense-functions, through which he sees, hears, feels, and moves without engaging his ordinary physical sensorium. The difference in waking or dreaming life lies, therefore, evidently not in the changes in the *ego* itself but rather in the respective media through which it manifests. Hence we find the same perceiving, judging, willing self-conscious center, the same powers of joy and sorrow, of approval and disapproval. Only the categories of time, space, and substance differ in the two conditions. Thus the sequence of dreams proceeds in neither past nor future tense, but unfolds in an interminable present, while space to the vision of the dreamer expresses an entirely new order of perspectives. The cause of this difference is to be found in the simple relation between the object perceived and the sense-function through which the perception takes place. In waking the perception objectivizes into form and substance, while in dreaming the same perceiver, by using different channels or media of observation, views things in terms of images and symbols.

In the phenomena of hypnotism and anæsthesia in general, a flood of light is thrown upon the genesis of sleep. If sleep is the result of a temporary shifting of a self-conscious center, then hypnotism and anæsthesia must from their very mode of operation be regarded as phases or aspects of the same vital process. In either case the departure of self-consciousness from its ordinary sensorium is preceded by cerebral anæmia, though the method of inducing the constrictor action differs in accordance to the agent initiating the process.

Now, in the case of general anæsthesia, the sleep-inducing drug, through the process of respiration, is brought into contact with the blood, and thence, through vasomotor action, is caused to exert an in-

fluence on the medulla. Responding to the impulse, the latter reacts by sending out a constrictor impulse along the fibers of vascular innervation. On functions under sympathetic control the effect of this reaction will, of course, amount to a mere passing phase, as the systemic balance of blood pressure is speedily restored by a rebound of the vasodilators. But on the cerebral consciousness, which is trembling in the balance of opposing powers, the shock from the constrictor action has a more intense and permanent effect. The dilator rebound fails to restore the circulatory balance, and anæmia dislodges self-consciousness from its operative centers. If the mind of the subject, however, is of a firm and positive nature, with a strong grip on its vehicle, it may successfully resist the mechanical or vital changes which in weaker minds would result in immediate surrender. Hence the different action of the same anæsthetic when applied to different individuals.

Principally, the action back of the anæsthetic sleep differs in no way from the action inducing the hypnotic sleep. The hypnotist, by engaging his subject in the monotony of visual, auditory, or tactile sense-impressions draws away his attention from the vital-dynamic relations, essential to waking life, thereby causing his mind to lose hold of its function. The cerebral mechanism thus released from self-consciousness is rendered receptive to the sympathetic life-impulse, becomes merged into the subconscious life, and goes to sleep. So far, hypnotism stands merely for an artificially induced sleep. But when the hypnotist, through the power of his will, usurps the field vacated by the mind, and introduces alien impulses into the cerebral life—impulses to be taken up, vivified, organized, and actuated by the sympathetic agency—a morally undiscerning and irresponsible factor—the process of hypnotism assumes its true ethical and moral significance.

For hypnotism by its personal character involves an element of motive, which gives to its operations a wholly unique and even dangerous character. The surrender of a hypnotized brain to the volition of an alien consciousness may permanently disturb the normal relations between the *ego* and its vehicle, and give rise to an enfeebled intellect. It may also occur that persons subjected to hypnotism become so habituated to hypnotic arrests of self-consciousness, that the mere sight of a bright object or the sound of a slight concussion may introduce the hypnotic state.

It has been stated by authorities on the subject that in a number of persons the susceptibility to hypnosis is found to be in an inverse ratio to the general mental development. According to Matthei, in the year 1815 only one person out of fifty was found refractory to hypnotism, while Professor Hansen in a recent lecture at St Petersburg, made the statement that at present only three out of ten fall under its influence. "The contagious psychic disorders and crimes of crowds," observes Manasseine, "as studied of late by Sighele, Le Bon, and Tarde, become less and less possible as self-consciousness predominates in a community, for what above all favors the propagation of such psychic epidemics is the presence of a considerable number of people with feebly developed self-consciousness—people of the spinal-sympathetic rather than the cerebrospinal type." And this because of the susceptibility of the feeble-minded people to the hypnotic currents of morbid moral and mental states, such as suicides, murders, superstitions, illogical theories, and general egotistical tendencies. Hence the susceptibility to hypnotism marks the same mental weakness of the individual, as the susceptibility to bacterial invasion marks his physical weakness. Hypnotism is a moral bacterium, and the only safeguard against its mental inroads lies in the maintenance of perfect moral and mental health, and the acquisition of high ethical and spiritual ideals.

The accuracy of a principle is evidenced by the universality of its application. This means that any expression falling within the range of a certain vital activity must find its true explanation in the laws and principles which are found to govern every separate phase or aspect of the phenomena as a whole.

Hence the principal back of sleep in general does not differ from any of its special aspects. The rendering of a part of the body insensible by injection of narcotics proceeds under the operation of the same principle of suspended or shifted consciousness as is involved in normal sleep. Only it is to be noted that in local anæsthesia the barrier to consciousness is not interposed between the cerebral and the sympathetic life, but between phases of the sympathetic life itself, and its adjusting center—the medulla. The narcotic agent has a power to rupture the chemico-vital associations which serve as conduits for the streams of sensuous life oscillating between the great sympathetic center and a given function. Hence in normal sleep, or anæsthesia in general, the cerebral consciousness is related to the medulla, as the latter in local anæsthesia is related to the part or function of the sympathetic system, subject to the narcotic action.

Yet the withdrawal of the sympathetic life does not leave the isolated function lifeless. The microscope reveals the presence of still deeper vital processes. Cellular action proceeds unimpeded by narcotic influence. The elaboration of protoplasm into cell-stucture is continued on all levels of manifested existence. Hence life, with its concomitant sleep, yields logically to the threefold division of a protoplasmic, sympathetic, and cerebral nature, with the phenomena of sleep marking off the ascendancy of consciousness to ever higher vehicles of expression.

The character of sleep must therefore naturally depend upon the degree of consciousness manifested in the stage of life related to it. Thus while the sympathetic system with its unruptured harmonious flow of life needs a sleep of mere oscillations, the cerebral system under the pressure of an aggressive self-consciousness requires hours of sleep for the rest and repair of its structural elements. And hence, while in the sympathetic system sleep proceeds without requiring a separation of its controlling consciousness (the medulla), in the cerebral system such a separation appears more or less necessary.

To sum up our argument, consciousness is the name by which we designate the power of life manifested under conditions appreciable to our intelligence, and when these conditions, in the course of evolution, have reached a degree of refinement permitting the expression of individuality, we call this expression self-consciousness.

Now sleep ensues when, in the course of individual development, the struggle of self-consciousness to control over larger fields of sympathetic life, wears out the material through which it manifests. From this it must logically follow that the amount of sleep needed by an individual depends on the intensity by which self-consciousness urges its mandate, *i.e.* attention, and on its power of volition in holding its own. With the increase of mental power and strength of character, the time allotted to sleep can be correspondingly decreased, which

finally would lead to a condition when, at the final conquest of cerebral self-consciousness over the sympathetic subconsciousness, sleep would be substituted by consciously and voluntarily administered rest.

The practical aspect in the study of sleep lies in the realization that existence is and becomes whatever we resolve to make of it. Self-consciousness is the crowning glory of life, and sleep is at once its means and impediments. By intelligently using it as means, we shall some day, in the course of universal evolution, overcome it as impediment. But the intelligent use of sleep is possible only through the intelligent use of life, which again means a devotion to universal and interhuman interests. "Not what I have, but what I do is my kingdom." The evolutionary man, the man of imperishable survival-value, is not the dreamer of dreams, but the doer of deeds. The man, to be of service to human life, must fashion the events to suit his purpose, rather than fashion his purpose to suit the events. He must learn to take hold of himself, to know himself, to lead rather than to follow, to administer rather than to be administered to—in a word to be a self-conscious factor in the higher evolution of the race, and to use time and space, sleeping and waking, as controllable and adjustable means for the attainment of the great end—the moral conquest of humanity.

ICTERUS IN SECONDARY SYPHILIS.

By B. C. HYDE, A.M., M.D.,
KANSAS CITY, MO.
SURGEON TO GERMAN HOSPITAL, ASS'T SURGEON TO ST. MARGARET'S HOSPITAL.

While icterus in secondary syphilis has long been known, the literature on this subject is comparatively limited. From the literature at my disposal it would seem that the number of cases reported have shown the condition to be also of comparative infrequence. Lausch reported 46 cases from literature and 3 of his own; Neumann 14; Lowenstein 1; Werner 57; Aschner 3; Jaumenne 2; Calvert 1; a total of 127.

The etiology of this disturbance is not known, and the various writers have not agreed on this point. The following have been stated as causes of the ichteroid manifestation: (1) Enlarged glands pressing on the bile ducts; (2) secondary eruptions in the intestines cause an obstruction in the flow of bile; (3) a general catarrhal condition, such as is found in other infectious diseases; (4) hyperæmia of the bile capillaries, due to inflammation of the liver; (5) changes in the blood and blood-vessels; (6) changes in the nervous system.

The jaundice varies from a slight tinge to a deep discoloration. Its course usually is accompanied by the customary secondary symptoms, but it may be unaccompanied by syphilides, as in the case reported below. Its character is not constant, and it may recur like the eruptions. Its duration is from a few days to a few months, and if untreated it may become chronic. It may assume a malignant type, and after the fifth or sixth day death may supervene, preceded by delirium, hemorrhage, purpura, or coma.

If the manifest secondaries are present the diagnosis may be easy, but in the absence of any of the syphilides, or in the presence of complications, the diagnosis may be difficult. The clinical proofs are the history and other syphilitic lesions. The best criterion for the diagnosis is the success of the anti-syphilitic treatment.

The following case came under my care on July 10, 1903: L. L., æt. 21, unmarried, bank-clerk, has a discharge from a gonorrhœa, which he contracted in March, 1903. In two or three weeks after the discharge began, a small ulcer appeared at the corona glandis, which was diagnosticated a chancre by a physician. At that time he was given anti-syphilitic treatment, without waiting for any secondaries, and he was also given anti-gonorrhœal treatment. There is slight adenitis of the inguinal glands on both sides. There is no scar at the site of the suspected chancre. Anti-syphilitic treatment was suspended to await secondaries, and treatment was directed toward relieving the gonorrhœa. He says he has lost weight since March.

July 29. Jaundiced. Nausea after meals. No vomiting. Discontinued work, but able to walk around. Phosphate of sodium prescribed. Discharge from urethra very slight. No pain in urethra. Has had slight left epididymitis during last few days.

August 4. Jaundice increased. Discontinued phosphate of sodium. Appetite fair. Sleeps well. No pain in region of bile ducts. No fever. No discharge from urethra. Left epididymitis giving considerable discomfort.

August 15. Jaundice increased, and very marked. Scleræ heavily stained. Stools light-colored and whitish. No skin eruption. Patient depressed and weakened. Inguinal glands enlarged on both sides and cervical glands can be palpated. Left epididymitis abated. Pain in intestines after meals. Temp. 99.4°. Suspecting syphilitic infection, I ordered potassium iodide gr. x, three times a day, increasing one grain each day.

August 18. Complexion slightly clearer. There is a slight papular eruption over scapulæ.

August 19. Pain in right epididymis. No discharge from meatus since August 4.

August 29. Complexion clearer. Jaundice slight. A slight papular eruption on face, probably from the iodides. There are a few mucous patches in mouth and a few papules on back. The appetite is good. He takes a hot bath every day and continues potassium iodide. Right epididymitis abated.

September 1. Skin clear. The remnants of jaundice seen in scleræ, which are slightly tinged. Appetite good. The iodide eruption on the face was a little more prominently seen, and accordingly all medicine by the mouth was discontinued and unguentum hydrargyri, ½ drachm was rubbed in once daily.

September 4. Condition improved. Inunctions continued.

September 14. Complexion normal. Scleræ clear. Inunctions continued. There is a slight papular eruption on face. There was no subsequent icteroid manifestation.

The patient concluded he would go to Hot Springs, Ark., where he was given baths, inunctions, and potassium iodide. He returned to Kansas City October 20, in good condition, but quite thin, complexion normal, the only complaint being two or three small sores in his mouth. He was given an iron tonic, and all the other medicine discontinued.

On October 27 the first symptoms of typhoid fever were noticed, and he died on the twentieth day of the disease, the immediate cause of death being hemorrhage of the bowels.

No autopsy was allowed.

Enlargement of the Spleen in Syphilis.—Sorrentino says that the almost constant enlargement of the organ during the first part of the second stage of syphilis may serve as a means of diagnosis when other symptoms are lacking. Morfan considers syphilis to be the chief cause of enlargement of the spleen in infancy, even more than in rickets. He had found it in about 50 per cent. of cases of congenital syphilis. Carpenter considers syphilis comes next to rickets as a cause of splenomegaly.

POLYMAZIA AMONG ENLISTED MEN OF THE MARINE CORPS.*

By RAPHAEL O. MARCOUR, M.D.,
ASSISTANT SURGEON, UNITED STATES NAVY

On the morning of January 26, 1904, while examining a patient in one of the wards of the hospital of the First Regiment, U. S. Marines, stationed on the Isthmus of Panama, I discovered that he had a supernumerary nipple and areola. I questioned the patient, and he informed me that he had never noticed that before. During the same afternoon, while overhauling some fifty men (who had been ill with fever), two more cases of polymazia came to my notice.

Case I.—W. F. F. Private marine, Co. G, First Regiment, U. S. Marines, age thirty-four years, native of Germany. Enlisted August 24, 1900, at Buffalo, N. Y. Somewhat emaciated; hair, dark brown; eyes, hazel. Normal nipples $\frac{1}{4}$ of an inch in diameter; normal areola (each) $\frac{3}{4}$ of an inch in diameter. Supernumerary nipple $2\frac{3}{4}$ inches below, and $\frac{3}{4}$ of an inch to the left of the right nipple; this nipple was $\frac{1}{8}$ of an inch in diameter; its areola was $\frac{7}{16}$ of an inch in diameter.

Case II.—W. H. R. Private marine, Co. C, First Regiment U. S. Marines age twenty-two years. Native of Cape May Court House, N. J. Enlisted September 26, 1903, at Philadelphia, Pa. Strong, and of good weight; hair, light brown; eyes, blue. Normal nipples $\frac{3}{16}$ of an inch in diameter, and normal areolæ $\frac{7}{8}$ of an inch in diameter. Supernumerary nipple $2\frac{1}{2}$ inches below, and $\frac{3}{4}$ of an inch to the right of the left nipple. This nipple was $\frac{1}{16}$ of an inch in diameter; its areola was $\frac{3}{8}$ of an inch in diameter. This person states that his attention was first called to this peculiar mark some time in October, 1902, while being examined physically, in Camden, N. J., for entrance in the Young Men's Christian Association.

Case III.—R. J. O. Private marine, Co. B, First Regiment, U. S. Marines, age twenty-two years and nine months. Native of Springfield, Ohio Enlisted September 8, 1903, at Scranton, Pa. Strong, and of medium stature. Hair, light brown; eyes, blue gray. Normal nipples, $\frac{1}{4}$ of an inch in diameter; normal areolæ, 1 inch in diameter. Supernumerary nipple, $2\frac{3}{4}$ inches below, and 1 inch to the left of the right nipple. This nipple was $\frac{1}{16}$ of an inch in diameter; its areola was $\frac{1}{4}$ of an inch in diameter. This person states that his brother, who is about twenty-five years old, has a similar mark on the left side of his body about the same distance from the nipple, as in his case.

All three of these supernumerary nipples were well marked, but were devoid of hair around the areola In this regiment there were 750 men and officers, and I am sorry that time prevented me from going over all the command, for probably more supernumerary nipples would have been discovered.

*Published by permission of Surgeon-General Rixley, U S. Navy.

Cost of the London Asylums.—What Londoners spend annually on doctors will probably never be known. But the report annually issued by the Metropolitan Asylums Board shows that they expend more than a million a year on the public treatment of imbeciles, the infectious sick, and the incidental establishment charges. Moreover, the sum, like the population, is annually increasing.—*The Daily News.*

The Action of Sunlight on Skin and Conjunctiva.—K Kreiblich presents a contribution to the pathology of the so-called hydroa vacciniforme and summer prurigo, both vesicular eruptions of the skin which are histologically closely related to the wheals of urticaria. He also reports two cases which were clinically distinct from the first-mentioned, but could be traced to the action of the sunlight. Both were marked by a course extending over several years and presented evidences of lichenification combined with eczematous eruptions. Connective-tissue infiltrations could also be traced to the action of the sun's rays, as they rapidly disappeared under an occlusive dressing. The author believes in addition that the catarrhal conjunctivitis met with in the spring is produced by sunlight, and suggests occlusive dressings as a curative measure and the wearing of red eyeglasses as a prophylactic.—*Wiener klinische Wochenschrift.*

Asthmatic Dermatitis.—T. B. Beddoes declares that it is well known that skin eruptions and rashes alternate with attacks of asthma. He reviews the opinions of a number of authorities on this subject. They associate asthma with urticaria, psoriasis, xeroderma, ichthyosis, eczema, and acne. Histological examination of the skin affections associated with asthma shows one common feature—alterations of the collagen, white fibrous tissue. The variability of the skin affections that accompany asthma is explained by there always being a change in the collagen of the cutis; following on this change in the cutis are other changes in the epidermis visible to the naked eye. In one case there is rapid alteration in the collagen, and localized œdema ensues, which produces the clinical manifestation of urticaria. Again, the change may be slower, so that fluid is effused on the surface, and eczema results. The slowest change is so tardy that the horny layer is increased, and there results xeroderma and ichthyosis. Cases of asthmatic dermatitis begin in early life—generally from eight to sixteen years. The association with acne may be only accidental. Later on in life this form of asthma ceases to give active trouble but leaves behind emphysema and a tendency to chronic bronchitis Asthma and skin disease, when associated, are relieved by thyroid: when they alternate, they are cured by it.—*Treatment.*

The Formation of Bone Tissue within the Brain Substance. A Contribution to the Inclusion Theory of Tumor Formation.—D. J. McCarthy speaks of the presence of true osseous tissue with all the histological structure of bone within the brain as being of great rarity. He reports experiments made to determine the results in the lower animals of constant cortical irritation. Small pieces of ser rated copper wire were sterilized and inserted beneath the dura of growing cats. In one kitten, a month old, the wire penetrated the brain substance near the superior longitudinal fissure, about 1 cm. behind the motor area. The animal died four months later after repeated convulsions. The brain was hardened in formalin and a section made through it at the point where the wire had penetrated. There was a hard mass the size of a small bean in this area. The growth was doubtless of recent formation. There was absence of calcification in the central areas of the tumor and the beginning of calcification in the peripheral areas. The growth was very vascular. There were capillary hemorrhages, round-cell infiltration, and rarefaction of surrounding brain tissue to be seen in the puncture wound. It would seem almost positive that the presence of the wire was in direct causal relation to the presence of the tumor mass. If this be true, the writer thinks that either a small bit of dura or periosteum, or possibly, some grains of bone from the needle opening, were carried down into the cerebral tissues with the wire, and as these tissues so early in life are very vascular and active, they continued to carry out their primary function of bone formation. There was no displacement of the bone and the tumor was $\frac{1}{2}$x$\frac{3}{4}$ cm., and of irregular spherical shape, so there could be no question of mere transposition of bone from the skull.—*University of Pennsylvania Medical Bulletin.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, Sept. 24, 1904.

THE COPPER TREATMENT OF PUBLIC WATER SUPPLIES.

POPULAR interest in the alleged purification of water supplies by Dr. Moore's copper treatment, as detailed in a recent bulletin of the Department of Agriculture, has been re-aroused by an epidemic outbreak of typhoid fever in the city of Washington. It appears that Dr. Moore has gone on record as stating that his method of treatment will infallibly destroy all typhoid germs in public water supplies, and that epidemics of water-borne typhoid fever are hereafter to be regarded as unnecessary. In support of his claim, Dr. Moore brings forward the results of certain laboratory experiments—which, by the way, are not known to have been verified by other observers, and also quotes extensively from letters from certain physicians who have successfully used copper salts in the treatment of typhoid fever; and he further refers to instances in which his copper treatment is alleged to have destroyed the algæ in large public water supplies. All these later claims have, of course, no relation to the question at issue, and their introduction by Dr. Moore tends to impair rather than strengthen scientific credence in his other contention relative to the infallible destruction of typhoid bacilli in drinking water, under any and all conditions. Briefly, Dr. Moore's method consists in adding copper sulphate to the water in such strength as to make a dilution of one in several millions. Usually, the proper amount of copper sulphate is placed in a bag and dragged, until dissolved, at the stern of a boat over the water supply to be treated. The same results, according to Dr. Moore, may be obtained by causing the water to flow over copper plates. The proportion of copper added to the water in any case is so insignificant, it is said, as to be negligible in connection with any effect upon the health of persons drinking water so treated.

In his original brochure, which appeared about six months ago, Dr. Moore was much more conservative in his claims than at present. He advanced the treatment as a means of destroying algæ—notably *Uroglena*, *Synura*, and *Asterionella*—and preventing the fishy taste and odor which such algæ impart to drinking water. The alleged positive germicidal effect of highly diluted copper solutions upon the bacilli of typhoid fever and cholera was touched upon, but the whole proposition of the distruction of algæ and bacteria by this means was apparently regarded at that time as experimental and requiring to be worked out under practical conditions on a large scale. To this end, the Department of Agriculture offered its assistance to municipalities applying for it. If, during the past six months, Dr. Moore has succeeded in getting that practical experience which was previously lacking, it is certainly unfortunate that in the present controversy he has not deemed fit so to inform his opponents and give the places, dates and results obtained. The claim is one of such far-reaching significance that it should be amply investigated without delay, and it furnishes a practical sanitary problem which it is earnestly hoped may be independently attacked by State and municipal boards of health through their chemists and bacteriologists. Pending the attainment of a more comprehensive and accurate knowledge of this matter, the health officer of Washington is to be commended for not being carried away by popular clamor. It is not that the occasional "dosing" of the drinking water supply of Washington, with the relatively infinitesimal quantity of copper sulphate recommended, would perhaps do harm to the health of the citizens of that city, but the knowledge that the water had been so treated would inevitably give rise to a certain fictitious sense of security and interfere with the carrying out in many homes of the certain and easy destruction of any typhoid germs by boiling. The time of a typhoid epidemic is not the time for the institution of untried and problematical measures of water purification.

If Dr. Moore has devised a simple and harmless way for destroying algæ in water, as seems likely, he has done a most important service. It is to be hoped that he has not allowed professional enthusiasm to entrap him into assuming a too advanced and untenable position with respect to the alleged easy destruction of typhoid germs in large public water supplies. Pending further investigation into this matter, Dr. Moore occupies the position of one who has either conferred upon humanity a boon of incalculable value, or one who has rendered himself and the Government bureau he represents ridiculous.

INVESTIGATIONS OF THE DIARRHŒAL DISEASES OF INFANCY.

THE Rockefeller Institute for Medical Research some time ago undertook the bacteriological investigation of children afflicted with various forms of diarrhœa. The investigation was carried out directly by twelve bacteriologists in the cities of New York, Philadelphia, Boston, and Baltimore under the supervision of Dr. Flexner. During the summer of 1902 Messrs. C W. Duval and V. H. Bassett undertook investigations for the purpose of studying bacteriologically the complaint known as "summer diarrhœa" of infants. These investigators reported the discovery in the dejecta and intestines of a high percentage of children suffering from this affection of a bacillus agreeing in essential properties with *Bacillus dysenteriæ*, Shiga.

A year earlier—the summer of 1901—Vedder and Duval investigated several outbreaks of dysentery in adults in this country, and found the dysentery bacillus in two institutional epidemics and a number of sporadic cases of the disease. The previous studies of Dr. Flexner upon tropical dysentery, made in 1900, had led him to experiment with the production of a vaccine of the dysentery bacillus, which experiments were later continued by Dr. Gay under the

direction of Flexner in the Pathological Laboratory of the University of Pennsylvania.

The experiments conducted during the summer of 1903 consisted in an exhaustive investigation of the bacteriology of diarrhœal diseases occurring in a large number of children.

The conclusions arrived at by Flexner, from a consideration of the findings of the various investigators, are as follows:

(1) *Bacillus dysenteriæ* can be isolated from the intestinal discharges and the intestinal mucosa of a large percentage of children suffering from the diarrhœal diseases prevailing along the Atlantic seaboard of the United States during the summer months. (2) *Bacillus dysenteriæ* is to be sought especially in the mucus thrown off by the intestinal mucosa in these diseases and in the substance of the mucous membrane itself. The bacillus exists in smaller numbers in, or is recovered with far greater difficulty from, the fecal matter that often is admixed with the mucus. (3) Blood admixture makes the isolation of the bacillus of dysentery from the intestinal discharges more readily accomplished, as it generally indicates infections of severer grade; but the mere presence of blood is of less moment than the occurrence of mucus, since it is in the latter material that the bacillus of dysentery resides. (4) The number of colonies of *Bacillus dysenteriæ* recoverable in cultures is in a general way indicative of the severity of the lesions and symptoms of the disease. Some cases, however, of marked severity yield few colonies, and others of marked mildness a larger number of colonies of the bacillus. (5) The total number of colonies of *Bacillus dysenteriæ* obtainable, is, as a rule, far below the number of colonies of the usual intestinal bacteria which develop upon the plates; but in a very few instances the number of colonies of the dysentery bacillus equals or exceeds that of all other organisms, and in exceptional specimens the bacillus alone appears in the cultures. (6) The type of *Bacillus dysenteriæ* which preponderated in the children is the so-called "Flexner-Harris" organism. The "Shiga" type of the organism is exceptionally met with, and occasionally both types are found in association. (7) Types of *Bacillus dysenteriæ* of less well-established properties have also been encountered. Among these are bacillus "*x*" of Hiss and Russell and another indistinct type which demands additional study before admission to the group, whose special property is its power to act upon lactose with acid production. (8) The blood of the children suffering from diarrhœal diseases agglutinates at times the bacillus of dysentery in high dilutions; but this agglutination by the blood does not proceed hand in hand with the occurrence of the bacillus in the intestine. The agglutination reaction is not to be treated as an index of the presence of, or infection with, *Bacillus dysenteriæ*. (9) The close association of *Bacillus dysenteriæ* with the intestinal mucosa, and the increased numbers of the organism found under definite pathological conditions, the established pathogenic action of the bacillus for human beings, and the specific blood changes met with in many of the cases of diarrhœal disease, all speak for a relationship of cause and effect between the bacillus of dysentery and the lesions of the intestine. (10) It is probable, although it is not proved, that *Bacillus dysenteriæ* appears at times among the saprophytic bacteria of the contents of the intestine. The frequency of its isolation in all grades of diarrhœal disease in children would be in conformity with the view of such a saprophytic existence and the acquisition, under pathological conditions, of pathogenic and invasive properties. (11) Should it be established that *Bacillus dysenteriæ* is occasionally or regularly to be found among the bacteria of the cavity of the intestine, the dangers of the entrance from without of specially pathogenic examples of the organism are not to be disregarded. The contagiousness of bacillary dysentery among adults and the rarer instances of diarrhœal contagion among children, prove the necessity of recognizing such an extra-infectious origin of the disease. (12) Streptococci in large numbers are found frequently associated in cultures with *Bacillus dysenteriæ*. Both organisms survive side by side and would seem not mutually to inhibit each other's development. What part is to be ascribed to each in the production of the lesions of the intestine and the symptoms of disease is not established by this investigation. Nor is the possible action of any other of the many bacteria of the discharges excluded by the special findings of the investigation. (13) The central fact brought out by this collective investigation is the frequent occurrence in the diarrhœal diseases of children of a specific microorganism, which hitherto has been held to be of special pathogenic action in human beings, and to be the cause of that form of dysentery among adults and also among children which is characterized by neurotic and pseudomembranous lesions of the intestine and marked infectiousness. (14) The lesions of the intestines observed in the children who have succumbed to the diarrhœal diseases treated of in this investigation have been very varied in character; but there has rarely been found among them the particular kinds of pathological changes which characterize pseudomembranous enterocolitis.

An important feature of the report was that Dr. Duval found the bacillus of dysentery in the stools of two healthy children. The intimate relationship of the bacillus of dysentery to the substance of the mucosa of the intestine, in which locality, under pathological conditions at least, it seems easily able to survive and multiply, is another fact discovered of considerable significance.

In the course of the investigation carried on during the summer of 1903, 412 cases of diarrhœal disease among children were studied bacteriologically with reference to the presence of the bacillus of dysentery. Of this number positive results were obtained in 279 or in 63.2 per cent. of all cases examined.

The conclusions arrived at by Duval and Bassett in 1902 were in part upheld, but that the character of the materials in which the bacillus is sought affects the result to the extent believed by these workers was not substantiated. Again the mere presence of blood in the stools is of less moment than Duval and Bassett supposed.

The Rockefeller Institute has commenced its work well and bids fair to develop into one of the foremost agencies of the world for the prosecution of medical research work. It has a

sufficiency of money to carry on investigations thoroughly, and the best known bacteriologists of this country are at its command. The result of its studies up to the present has been encouraging, and the reports of the several investigators on infantile diarrhœa form a valuable contribution to the literature on the subject.

Jaundice and Its Treatment.

Dr. William Henry Porter, at a meeting of the New York Post-Graduate Clinical Society, held last spring, read a paper on obstructive jaundice, in which he considered the subject from the medical point of view and summarized as follows: (1) All forms of jaundice are due to obstructions of the ducts; (2) there are two distinct forms: one in which the obstruction is within and one in which it is outside the liver; (3) some are amenable to surgical interference only; some to medical treatment only; some can be reached by medicine and by the surgeon's knife; (4) the intralobular occlusion form bears surgical interference badly; while the extrahepatic form usually does well under the surgeon's knife. The intralobular occlusive variety of jaundice can be treated successfully only by medical measures. In this class the digestion must first be improved, and the abnormal fermentative processes in the intestines arrested.

According to the author, the cardinal principle governing the dietetic treatment of these cases is, that the different classes of foodstuffs, such as the starches, sugars, fats, and proteids, must be furnished in such quantities only that the digestive functions will not be overtaxed, nor the oxygenating capacity of the system exceeded. In some the exclusive skimmed milk or buttermilk diet is the most valuable; this to be followed as soon as fats can be assimilated, by unskimmed milk. Some will be able to take with the milk, beef tea and plain meat broths. Raw eggs are very serviceable in these conditions. As soon as the system will digest them, cooked eggs and meats should be given, and last of all bread, in the form of dry toast or plain wheat bread from twenty-four to forty-eight hours old. If milk in its natural state cannot be tolerated, some form of fermented milk may be ingested. Beefsteak is taken as the standard meat to work from, as it is the most easily digested and assimilated. Dr. Porter strongly warns against the eating of fruit and many of the vegetable foods in all forms of intestinal indigestion, as these give rise to acidity and fermentation. Even with the diet carefully regulated, nature unaided is unable to digest perfectly the foodstuffs, which must, therefore, be artificially digested within the elementary tract.

An indispensable factor in the successful treatment of jaundice is that the bowels should be kept in good working order. Movements should be secured from one to three times a day. When the bowels fulfil their functions freely, the toxins will be carried out with the fæces, and their liability to enter the blood-stream is reduced to the minimum. The cathartics and antiseptics, in the opinion of the author, work best when combined with the bile and pancreatic extract, and should be administered before each meal. The sluggish action of the heart and circulation is best overcome by the use of muriate of caffeine and strychnine. Last, but not least, in the treatment, is that which directly influences the enlarged and degenerated cells of the liver, which are occluding the biliary radicles. These are best reached by calomel in varying doses alone, or in combination with arsenic, bichloride of mercury, and ipecac. Another point to be borne in mind in the treatment of jaundice is that all patients do best when they are in the open air and light. On occasions, a stay in the country, at a considerable altitude, will work wonders with a person suffering from jaundice.

In the discussion which followed the reading of Dr. Porter's paper most of the surgeons present took exception to the opinions expressed as to the need of medical treatment alone for intralobular jaundice. They argued that the author laid too much stress on intestinal fermentation as a cause of the condition, and contended that intestinal fermentation plays by no means so prominent a rôle in jaundice as implied by Dr. Porter. Surgeons are more and more frequently invading the domain of medicine, and the treatment of intralobular jaundice by surgical measures is a matter of not uncommon occurrence. As to whether the surgeon is not apt to use the knife with somewhat too great freedom, is a point which is open to discussion. Bold measures are indicated in desperate cases, but on the whole, perhaps, a judicious conservatism meets all phases of the situation the best.

Destruction of Rats and Mice.

The Pasteur Institute, according to United States Consul-General J. K. Gowdy at Paris, claims to have discovered a method of destroying the rats and mice which have almost decimated vines and crops. Mr. Gowdy says that the claims of the Institute can be established by facts, so far as the destruction of rats and mice is concerned, but it does not yet appear to be proved clearly and unmistakably that the means employed for destroying animals mentioned is not hurtful to other forms of animal life to be found in agricultural and vine districts. However, the results so far obtained have been entirely satisfactory to the French Government.

On the 28th day of January last, Drs. Roux and Chamberland, in company with a general inspector of agriculture, proceeded to the Department of the Charente, which district has suffered most severely. Dr. Roux brought with him to the scene of operations a large quantity of "bouillon" swarming with rat microbes. He and his assistants dipped quantities of wheat, oats, and small pieces of bread, about 0.3937 inch square, into the bouillon and which immediately became impregnated with the microbes which the bouillon contained. Then the poisoned wheat, etc., was placed in and about the holes in which the rats and mice were known to be. The quantity of poisoned "paste" distributed amounted in all to 4.2 metric tons of bread and 9.3 metric tons of oats, while the quantity of bouillon used was 1,190 bottles. The total area of these experiments was 2,965 acres. To determine the effect of this poisoned paste on the animals, Dr. Roux had the fields ploughed up in order to see the condition of the rodents after they had eaten the paste and to fix approximately the number of rats and mice that had succumbed to the poison. The results obtained surpassed all expectations on the part of the farmers. Rats and mice were dead in almost alarming quantities, and became quite as much of a pest when dead and putrefying as when they had been alive, but happily in another sense of the word. Dr. Roux estimates that he destroyed no less than 95 per cent. of the rodents by these experiments.

The minister of agriculture, being satisfied with the results thus obtained by Dr. Roux, and acting on the advice of the eminent scientist, proposes to

introduce into the Chamber of Deputies a bill for the purpose of compelling farmers in rat-infested districts to coöperate in using the above-described paste.

Subcutaneous Injections of Mercury for Syphilis.

In the *Scottish Medical and Surgical Journal* for May, 1904, notice is taken of this method of treatment of syphilis. In England, and especially in Scotland, such treatment is little used, although the medical services pursue it. In the article referred to, the objections to the method are discussed, a recent lecture by Julien at the University of Paris, supplying the subject matter. Julien has used the injections for twenty-five years, and is a strong advocate of the treatment.

The objection most usually brought against injection is the risk of the formation of abscesses at the seat of puncture. According to Julien, these occur only when calomel is used. They are, however, becoming increasingly rare, with the more general improvement in technique. Julien nearly always uses the insoluble, and less quickly absorbable, preparations. The three that he uses are calomel, gray oil, and the insoluble salicylate. When rapid, powerful action is required, calomel is used. For slower action without any danger of intoxication, he prefers the salicylate or the gray oil. The dose of calomel should depend on the weight and condition of the patient. Thus, one grain is about the dose for a patient weighing 132 pounds. As a rule, the first three or four injections should be given at intervals of eight days. Later, the intervals should be prolonged to ten, twelve, and fifteen days, and finally to a month. Gray oil is more active than the salicylate. A course of four to six hypodermic injections of about $\frac{1}{5}$ of a grain of mercury, at intervals of eight days, should be given three or four times a year. Julien remarks that the salicylate is remarkable for the wonderful tolerance for it exhibited by all the tissues.

Mercurial treatment should be continued for at least five or six years after the acquirement of syphilis, by monthly injections. Julien claims two great advantages for injection, especially of calomel: (1) For the rapid diagnosis of syphilis in cases in which there is a question of operative interference, if the condition should prove non-syphilitic. This therapeutic test is now recognized in France as one of the best. (2) It is certain that it produces an abortive effect upon syphilis, in many cases, if used at the very beginning of the disease.

Flash-light Signs.

A new form of electric sign has been introduced in this city lately, which should be suppressed now before it becomes general. We refer to the large-lettered electric-light sign which flashes out brilliantly for a few seconds and is then extinguished for an equal period. The effect of this alternation of light and darkness is most trying, not only to the eyes of the passers-by, but also and especially to residents in the neighborhood whose windows look out on the signs. One may sleep in a bright light or in darkness, but no nerves can stand the strain of a momentary illumination of the sleeping apartment recurring several times a minute. This is a nuisance which it would seem to be within the province of the Board of Health to abolish, and the Commissioner may well give his attention to it while as yet the offenders are few.

News of the Week.

Fifteenth International Medical Congress.—We have received the second and third numbers of the Official Bulletin containing a report of the work of the Committee on Organization. We learn from this that the work is progressing favorably and that, so far as it lies in the power of the committee, the day the congress opens will see everything ready and in good running order. Two members of the committee have died since its formation. The first death was that of Prof. Costa Simões of Coimbra, which occurred in November of last year. The second was of Prof. Hygino de Sousa, secretary of the Section on Ophthalmology. During the sessions of the congress a Colonial Exposition will be held in Lisbon under the auspices of the Section on Colonial and Naval (Tropical) Medicine. The Section on Psychiatry has begun an investigation on pellagra in Portugal, the conclusions of which will be ready for presentation to the congress.

Impeding the Work of Sanitation on the Isthmus.—It is stated in the *Herald* that the sanitary work of Colonel Gorgas on the Isthmus is being seriously hampered by the unreasonable opposition of General Davis. It has been a matter of comment that the military insisted upon appropriating all the supplies consigned to the sanitation department and refused to give them up except on requisition made in the usual manner in the army. Colonel Gorgas is also reported to be aggrieved over the treatment given to the nurses at the hospital. They went to Panama under stipulated salaries, but at the end of the first month were notified by the governor of a reduction. We hope these reports are exaggerated, or else that Colonel Gorgas, who is now in this country, has obtained assurances from the authorities in Washington that he will be allowed a freer rein in his arduous task. It will not do to risk a yellow-fever outbreak by tying up with red tape the man who has proved that he can prevent it if given a free hand.

First Aid in Chicago.—Plans to train the public in the science of rendering first aid to the wounded in emergency cases are being pushed by a newly-formed organization of physicians and laymen, the Chicago First Aid Society. This society has undertaken to make an organized effort to deal with our appalling and ever-growing casualty list incident to the rush and hurry of modern industrial life, and it proposes to establish throughout Chicago classes of instruction in first emergency methods for the treatment of the injured. The following physicians and surgeons compose the medical board: Drs. Nicholas Senn, Chas. Adams, R. N. Foster, Arnold C. Klebs, Henry B. Favill, James B. Herrick, N. S. Davis, S. C. Stanton, John Ridlon, John B. Murphy, Wm. E. Quine, and Geo. W. Webster. The course of instruction will consist of a series of about fifteen lectures. These lectures will include a short elementary course in anatomy and physiology, to be followed by demonstrations and instructions in the correct emergency methods of treating broken bones, sprains, and dislocations; how to arrest bleeding and treat wounds and cuts; instruction in bandaging; how to treat shocks of electricity and lightning, etc. At the end of the course examinations will be held and certificates and badges awarded to graduating members. There will be no charge for instruction.

Opening of Columbia University Medical School.—The opening exercises of the academic year 1904–5 of the College of Physicians and Surgeons will be

held in the Lower Lecture Room on Thursday, September 29, 1904, at 3 o'clock P.M. After a brief address of welcome by the President of the University, an address will be delivered by Dr. John G. Curtis, Acting Dean and Professor of Physiology, upon "Our Medical Training in the Light of Ancient Error."

Cornell University Medical School.—The work of this college for the year 1904–5 will begin on September 28. The number of students registered for the first-year class is greatly in excess of that of any previous year; it is noted also that the preliminary education of the applicants is improving. Dr. Frederick Whiting has been appointed professor of otology in place of Dr. Gorham Bacon, resigned, and Dr. Adolf Meyer professor of psychiatry in place of Dr. Allan McLane Hamilton, resigned.

Use of Dum-dum Bullets Suspected.—The Japanese have several times declared their belief that the Russians are using the prohibited dum-dum bullets, this belief being based on the nature of the wounds received. This bullet resembles the ordinary service bullet, except that the leaden core is left uncovered, and, by further making the bullet weak at the apex, it spreads out immediately on striking a bone, usually with fatal results. In partial confirmation of this suspicion, Marquis Oyama states that among the ammunition abandoned by the Russians at Liao-Yang were two kinds of dum-dum bullets, each resembling those for the 1891 pattern Russian rifle.

Church Quarrel over a Hospital.—There is much opposition on the part of certain Roman Catholic priests in Orange, N. J., to the project of the rector of the Italian church to establish a new hospital in that city. The cause of the opposition to Father Ronanelli, the Italian priest, is not made public. According to present plans the hospital will be ready for patients early in November.

Increased Powers of the State Board of Charities.—The New York State Board of Charities recently wrote to the Attorney-General asking his opinion as to its jurisdiction over certain institutions in the State which are in receipt of public money, but which are apparently private business enterprises rather than charitable institutions. In his reply Mr. Cunneen says that whenever a public agent employs a private individual or corporation to "care for, support or maintain" one or more persons at public expense the service must be rendered "pursuant to rules established by the State Board of Charities," and that the State Board has all the powers of visitation and inspection necessary to enable it to know whether its rules are complied with. The board, however, has nothing to do with the general business or affairs of an individual or corporation, because he or it may incidentally render a public service.

Opposed to the Carbolic Acid Law.—Pharmacists in New York are aroused by the recent amendment to the Sanitary Code prohibiting the sale of carbolic acid at retail in any more concentrated form than a five-per-cent. solution. The complaint of the druggists is that the prohibition of the sale of the acid, while it will not make suicides more difficult, will inflict a great hardship on the public, who use carbolic acid more than any other agent for disinfectant purposes. At the same time they assert that an intending suicide can go to a wholesale drug house and buy the acid in the original package without question, and a child can do this as easily as an adult. But one who resorts to carbolic acid, usually a woman, for suicidal purpose, generally does so on the impulse of the moment, and if she had to go to a wholesale drug house to get it, she would either get over her wish to kill herself or would find some other means to effect her purpose. In the notice of the new carbolic acid regulation it is stated that if carbolic acid is found by the side of the dead in a bottle bearing the name of a drug firm, the department will take action against such druggist.

Radiotherapy of Cancer.—One of the principal discussions at the International Dermatological Congress, held last week in Berlin, was that on the treatment of cancer. Professor Peterson advocated the ray treatment of epithelioma, but admitted that it was curative only in the early stages of the growth. He preferred the Finsen light as being the safest method, and held that the *x*-rays and radium, though efficacious in many cases, were dangerous and should be employed with great caution. Prof. v. Bergmann was opposed to the trial of radiotherapy in operable carcinoma. He said that any superficial epithelioma could be cured in the early stages by the knife, but only a certain proportion of such cases were amenable to radiotherapy, and he asserted that no inoperable cancer had ever been cured by the *x*-rays or other form of radioactivity.

Dr. Fred W. Lamb has been appointed curator to the Cincinnati Hospital Laboratory to replace Dr. Wm. Muhlberg, resigned.

Professor Escherich in America.—At a special joint meeting of the Chicago Pediatric and Chicago Medical Societies, held September 17, Prof. T. Escherich of Vienna addressed the society on "Tetany in Infants." In the morning of this day, Professor Escherich gave a public medical clinic in the amphitheater of the Cook County Hospital.

Journal of the Medical Society of New Jersey.—The first issue of this journal, the latest among the State medical papers to make its appearance, has been published under date of September, 1904. The editor of the journal is Dr. Richard C. Newton of Montclair; the committee on publication consists of Drs. William J. Chandler, David C. English, and Henry W. Elmer. The first issue contains the address of the President delivered at the annual meeting of the society in 1904.

Dangers of Elevators.—At a recent inquest into the death of a man resulting from the fall of a freight elevator, the coroner said that since January 1 there had been thirty persons killed and many more injured in New York City by faulty elevators. He believed it was time that something was done to lessen the number of these accidents.

Diphtheria in Newark, N. J., has increased markedly in the past two or three weeks, and it is feared, now that the schools have opened, that a still greater number of cases may be reported. In the week ending September 3 there were twenty-seven cases of diphtheria in the city, in the following week fifty-three cases were recorded, and during the week ending September 17 there were over sixty cases. The Board of Health urges the extensive use of antitoxin. It also suggests that whenever one member of a family is suffering with the disease every other inmate of the household shall be inoculated.

Pasteurized Milk Distribution.—The summer season of the Strauss pasteurized milk depots closed last Saturday. The number of bottles of pasteurized milk distributed was 2,149,194, and in addition upward of 800,000 glasses of milk were sold at the booths in the parks and on the recreation piers. The demand was greater in the past summer than in any of the previous twelve years in which the work has been carried on, the increase being nearly

half a million bottles over 1903. The season was also notable for the inauguration of the work in St. Louis.

Sir Felix Semon Banqueted.—On September 15 a dinner was given to Sir Felix Semon at the Chicago Club by the members of the Chicago Laryngological and Climatological Society.

The Russian Sick and Wounded.—Reports of the Red Cross work among the Russian troops in Manchuria show the following proportion of patients suffering from wounds or disease out of the total sent to the hospitals in the area of the military operations: Cases of severe illness, 10 per cent.; slight illness, 56 per cent.; wounded, 34 per cent. The only epidemic disease noted is dysentery, with 6 per cent. of cases.

Prof. A. Wassermann of Berlin will deliver an address, in German, before the New York Pathological Society at a special meeting to be held at the Academy of Medicine on Wednesday, September 28, at 8.30 P.M. The subject of the address will be "A Discussion on Several New Points Concerning the Theory and Practice of Immunity."

Obituary Notes.—Dr. JACOB CHAMBERS of Kingston, N. Y., died at his home in that city on September 15, at the age of fifty-two years. He was a graduate of the Medical Department of the University of Buffalo in the class of 1875. He was on the surgical staff of the Kingston Hospital. He had for many years been the family physician of Judge Parker, the Democratic nominee for the presidency.

Dr. HENRY RIDGLEY of Dover, Del., died on September 17 at the age of eighty-seven years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1839. He had been prominent as a banker as well as a practitioner of medicine.

The Different Kinds of Typhoid Fever Relapse.—Maurice Coste gives Hutinel's classification of the relapses of typhoid fever—simple and pyretic on the one hand, anomalous relapses and relapses associated with wide oscillations of temperature on the other. The simple relapse recalls in its course an ordinary attack of enteric fever, but the symptoms are generally less severe and less marked. The temperature may rise suddenly to its maximum, or it may rise rapidly in "staircase fashion." The fastigium may present several types also, the oscillations being of the regular or irregular remittent, or regular intermittent type. The eruption appears earlier than in the original attack, generally between the second and fifth days. The pyretic relapse differs from the four just described in the absence both of typhoid symptoms and complications. It is manifested by a rapid rise of temperature during convalescence. The temperature can be accounted for only by the action of the typhoid poison on the system. In the anomalous relapses, the temperature curve may present still greater oscillations of temperature. In this variety of relapse, which is by far the commonest, the temperature rises continuously and attains its maximum about the fifth day, between which and the eighth day it remains steady; but on the ninth day it suddenly drops several degrees and may even become subnormal, though it subsequently rises again to its previous level. The temperature remains slightly raised until the fifteenth day, when it again falls suddenly, and oscillates slightly until the twenty-first day, when convalescence sets in. However, the temperature does not always follow this course. The characteristic feature of this type is the irregular course of the temperature and the late appearance of the eruption (tenth day). In the relapses associated with wide oscillations, the difference between the morning and the evening temperatures may amount to from 4° to 6° F. The treatment of the relapse does not differ from that of the original attack.—*Medical Press and Circular.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ROYAL COMMISSION ON EPILEPTICS, ETC.—INFECTIOUS HOSPITALS—RESTORATION OF THE APPARENTLY DROWNED—ITEMS.

LONDON, September 2, 1904.

IT was announced yesterday that the King has appointed a royal commission to consider the existing methods of dealing with idiots and epileptics and with imbeciles, feeble-minded, or defective persons not certified under the lunacy laws; and, in view of the hardship or danger resulting to such persons and the community from insufficient provision for their care, training, and control, to report as to the amendments in the law, or other measures which should be adopted in the matter, due regard being had to the expense involved in any such proposals, and to the best means of securing economy therein.

The commission is hardly a strong one, but fairly constituted as such appointments go, but one would have expected to see more than one M.D. among its members. It is something, however, to see a royal commission on a medical matter.

A question which has for three or four years been intermittently mooted is now exciting attention, both within and without the profession. It is whether the system of isolation hospitals is of any use in reference to scarlet fever. At the recent meeting of the Royal Institute of Public Health there was a discussion on the subject, and the following resolution was carried by thirty-six votes to twenty: "That, as the hospital isolation of scarlet fever has now been tried on a large scale, for a number of years, and as some doubt exists as to whether the results obtained are commensurate with the cost, it is desirable in the public interest that a full and authoritative inquiry into the subject should be held." Although the minority in this division is a strong one, the significance of the numbers is impressive when one remembers that two or three years ago such a motion would have been laughed out of any meeting of sanitarians. In fact, a proposal for inquiry was made by one or two health officers and their suggestions met with an opposition worthy of party politicians. Why doctors and scientists should adopt such an attitude may not appear on the surface, and is a problem perhaps not worth attempting to solve. But the question is one of importance to the public as well as to investigators, and deserves to be considered in the light of dry science. Gentlemen who pose as sanitarians ought not to indulge in contemptuous language toward those who differ from them in opinion, and both sides may as well remember that assertions are not arguments. The great importance of the subject may be seen in the fact that our fever hospitals were erected mainly for the purpose of isolating scarlet fever in the hope of thereby preventing its spread. But these buildings, erected at enormous cost, have proved rather homes for patients during the disease, which seems as prevalent as ever. These hospitals have not diminished diphtheria in the population; that disease has greatly increased since they were established; no one denies this. Why, then, should we not inquire whether we have adopted the right method of dealing with scarlet fever? Is it possible that hospital treatment is unfitted to cope with either or both these diseases? One thing is certain, our fever hospitals are not isolation hospitals, as they are often miscalled. Isolation can be achieved in many a private house; in hospitals never. Institutional treatment substitutes aggregation for segregation.

We are at present living during a period of mild type of scarlet fever, but there is no certainty that this will continue long. We can never predict when a severe epidemic will break out. Still less can we state what are the conditions which produce variations of type. The stoutest defenders of the hospital system do not dare to claim for it the mildness of the type now prevailing or the decrease of mortality resulting. They rather plead that cases are better nursed and attended to than they can be in the average home; but as to that I should like to know what they consider an average home.

It is easy to picture to oneself a home in which a patient would be infinitely better off in his own home, but it is equally easy to speak of cases in which the home does not deserve the name and affords no hope of restricting the infection. Much has been made of what are called return cases, when patients discharged from hospital as recovered and disinfected have carried the infection with them and set up a fresh focus whence the disease has again spread. But these cases are comparatively rare, and with increased care will diminish in number; and home-treated persons are perhaps more often the source of fresh outbreaks. Another danger of hospital cases is that occa-

sionally a patient may contract another infectious fever or even convey it home on leaving. We have had an abundance of statistics of towns, and they do not seem to prove that those where isolation is in vogue have enjoyed more freedom from the disease than those where it is not attempted. The difficulty of diagnosis must not be overlooked. The mildest attack, which is perhaps dismissed as a mere sore throat from catarrh, has not seldom been the first case of an epidemic.

Bathing accidents are of almost daily occurrence, and so we again discuss the methods of reviving persons apparently drowned. The Sylvester and Marshall Hall methods are mostly employed, but Professor Schafer condemns them and upholds a modification of the Howard system. Instead of turning the patient on his back after the first pressure for forcing out retained water, he advises keeping him on his face. This prevents the tongue falling back and closing the larynx, and offers less risk of injury to internal organs by the pressure. Moreover, he holds that artificial respiration so performed effects a maximum exchange of air between the lungs and the atmosphere. The operator's hands being placed on the lowest ribs, he can carry on artificial respiration in the prone position without risk to the internal organs.

The new Sydenham society held its forty-sixth annual meeting at Oxford, Professor Osler presiding. The Clinical Atlas of the Society has, for several years, been put forward as its strongest claim for support, and now it is determined to prolong the issue indefinitely. This naturally absorbs a large proportion of the income, but it is hoped that one printed volume per annum may be issued in addition to four fasciculi of the Atlas. Each plate will, when possible, be complete in itself, but it is not to be considered that any subject will be completely treated in any fasciculus. Dr. Osler expressed great satisfaction at the decision to prolong the publication of the Atlas. These clinical illustrations of disease and the standard works distributed to subscribers are certainly of great value, and it is desirable that the society should increase the number of its members.

Mr. Allardyce, late acting-governor of Fiji, recently lectured here on the curious subject of fire-walking in Fiji, Japan, India, and other places. This power of walking on hot stones, wood, embers, etc., has been claimed from early times. The Hirpi, according to Horace, performed the feat; Iamblicus, in the early Christian period, attributed the power to mediums, and Home, in our own time, seemed to handle red-hot coals in the presence of Sir Wm. Crookes. Mr. Allardyce does not accept the explanations offered by Dr. Rob. Fulton, in the Transactions of the New Zealand Institute; and Mr. Andrew Lang rather chaffs scientific men who have investigated the matter with their reluctance to adopt the test of following in the footsteps of the performers. Dr. Hoeken suspended a thermometer over the pit but it melted, and we hear no more of thermometrical experiments. He and Dr. Smith examined the feet of one of the performers before he entered the pit and found them colder to touch than the rest of the body, but do not seem to have used a thermometer. The soles of the feet were like soft kid, which certainly does not seem the sort of surface for walking on white hot stones. Dr. Fulton got one of the stones and could not hold it in his hand after he had cooled it in the sea for several minutes. Mr. Lang wants to know why the scientific gentlemen who offer various explanations do not do as Colonel Gudgeon and his companions did; who walked with the natives of Raratonga "merely not to be beaten by persons of color." The Colonel reported a sensation of slight electric shocks. Mr. Lang says the savant would be as safe as the Fijians or his explanation amounts to nothing.

"He either funks the fire too much,
Or his belief is small,
Who dares not put it to the touch
To win or lose it all."

The death rate of Liverpool, which has been so high as to cause much anxiety—at one time reaching thirty-nine—fell during the past week to twenty-nine.

A child was attacked by a game cock and one of its spurs seems to have penetrated the skull. Cerebral abscess followed, as testified at the inquest, and a verdict was found accordingly. Another unusual death is also reported—that of a man who was stung by a wasp in the throat when drinking beer, the rapid swelling obstructing the larynx.

Twenty-eight medals have been awarded to retired non-commissioned officers for meritorious service; of these eight have fallen to men of the Royal Army Medical Corps.

Dr. Barton has quite recovered from his accident, and yesterday demonstrated the details, construction, and management of his air-ship to the members of the Aëronautical Society.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

PERCUTANEOUS ADMINISTRATION OF IODOFORM IN PULMONARY TUBERCULOSIS—ANURIA DUE TO HEMORRHAGIC PLUGGING OF THE URETHRA—SUPPURATIVE SINUSITIS—THYROGENOUS TETANY—PATHOGENESIS OF ENDOCARDITIS—DORSAL AUSCULTATION OF THE HEART—PRECOCIOUS DEVELOPMENT—BILATERAL MOVEMENTS—CUTANEOUS TUBERCULOSIS—CURE OF EPITHELIOMA BY RADIUM RAYS—DEATH OF PROF. ANTON DRASCHE.

VIENNA, August 24, 1904.

A NEW method of treating pulmonary tuberculosis has been advanced by Dr. E. Ganea in Steys. Briefly the method is as follows: Ganea uses an ordinary syringe, which is, however, fitted with a sieve-like attachment to be applied firmly to the skin immediately above the infected area in the lung. The fluid injected is a solution of iodoform in the other. The fluid is drawn into the barrel of the syringe, and the latter is fitted into the attachment, the bottom of which is perforated like a sieve. Fairly high pressure, evenly applied, forces the fluid gradually into the muscular layer without apparently injuring the skin. The iodoform is carried to the tuberculous focus and exerts its action upon it. Ganea hopes by this method to inhibit the multiplication of the tubercle bacilli, to limit the growth of the infected areas, and to excite processes of calcification.

At the meeting of the gynecological section of the Budapest Royal Association of Physicians, Kubinyi presented a case of anuria due to varicose hemorrhage into the bladder, with subsequent formation of clots. The hemorrhage occurred after the patient, eight months pregnant, had lifted a heavy weight. The anuria lasted several days, and a merely tentative diagnosis could be made. After dilating the urethra and perforating the clot, the urine, which amounted to several liters, and threatened to rupture the bladder, was evacuated with considerable difficulty. All symptoms disappeared immediately and a cystoscopic examination after delivery confirmed the diagnosis, revealing a dilated vein and alongside of it a dark spot on the mucosa, the probable site of the hemorrhage. Numerous varicose veins were observed on the lower extremities.

Polyak demonstrated a case of multiple suppuration in the accessory nasal sinuses with formation of bone cavities and bilateral atrophy of the optic nerve; the process lasted for five years and simulated a neoplasm. There was occlusion of the left nostril. After the lapse of one year a left-sided amaurosis developed, with protrusion of the left eyeball; later, the same symptoms appeared on the right side; there was also descent of the palate, with deformity of the face. It proved to be a latent suppurative process in the ethmoidal cells, extending into the sinus of the left middle turbinated bone, and accompanied by the formation of bone cavities. Under great pressure the pus entered the posterior ethmoidal cells, and the left sphenoidal sinus, and later the right sphenoidal cells, producing protrusions of the eyeballs with atrophy of the optic nerve. Operation gave exit to 200 c.c. of pus.

A case of thyrogenous tetany, occurring in consequence of lactation, was shown by Ferenczi. The patient, a woman of thirty-six years, mother of seven children, showed a beginning cystic degeneration of the thyroid gland during her second pregnancy. Since then she has suffered from tetany during each period of lactation, the attacks gradually disappearing when the child was weaned. The treatment consisted in the administration of thyroid extract, which the speaker held should be used in every case of lactation tetany, even when no degeneration of the gland can be demonstrated.

Dr. F. Prochazka in Prague, has made some interesting investigations regarding experimental endocarditis. He injected dogs subcutaneously with certain toxins (typhoid, diphtheria, etc.), and when toxæmia resulted, he made intravenous injections of cultures of such organisms as are regarded causative of endocarditis. Nine out of ten experiments were positive, *i.e.* an inflammatory reaction could be demonstrated both macroscopically and microscopically at the sites usually selected by an endocarditis. Both the verrucose and ulcerative varieties were found. Control animals, who were injected only with the toxins, showed no endocarditis; on the other hand, the injection of pyogenic organisms led only to general sepsis rarely localized in the endocardium. These experiments prove that, in addition to the presence of pathogenic organisms, a certain predisposition is necessary, which is created by the toxins. The fact that experimental endocarditis selects the same sites as a natural endocarditis, emphasizes the importance of the mechanical causes of this lesion (such as friction, impact, etc.).

Methodical dorsal auscultation has convinced Dr. W. Libensky that this method enables one to draw certain

conclusions as to the condition of the heart. Lesions of the left auricle give a murmur which is heard loudest at the lower angle of the left scapula. Dilatation of the right heart forces the left ventricle away from the anterior chest wall, turning it inward and backward until it approaches the posterior chest wall. The greater the dilatation, the more unfavorable the prognosis, and the clearer the physical signs. With lesions of the left ventricle, the murmur is heard loudest in both supraspinous fossæ and downward to the third dorsal vertebra; it is inaudible at the angle of the left scapula. This physical sign is, therefore, of great diagnostic importance, especially in relation to the degree of dilatation of the right heart, and it has also a bearing upon the prognosis.

Before the Society of Bohemian Physicians at Prague, Dr. J. Lenz presented a unique case of precocious evolution, the patient being a girl of six and one-quarter years. At birth she was larger than her brothers and sisters, and developed very rapidly. At four months there was distinct swelling of the breasts and hemorrhages from the genitals, which after the sixth month, recurred regularly every four weeks. A growth of hair in the axillæ and over the pubes began at eighteen months. The child is 127 cm. long, and weighs 26.5 kilograms. The mammary glands have a diameter of 14 cm.; they are hemispherical. The nipples are large and surrounded by large, pigmented areolæ. The uterus is only slightly enlarged, but the left ovary is large and nodular. The pelvic shows all the changes characteristic of puberty, the distance between the iliac spines being 24.5 cm., between the iliac crests 25 cm.; the bitrochanteric measurements are 24.5 cm., the external conjugate 15 cm. The epiphyses of the femora are ossified and the ilium, ischium, and pubis are fused in bony union.

At the Vienna Medical Society, Dr. Fuchs demonstrated the rare phenomenon of double motion in a girl of seventeen, whose nervous system was in all other respects perfectly normal. In earliest infancy the mother noticed that the child grasped for all objects with both hands. Later this motor disturbance was limited chiefly to the fingers. Every motion which the patient executes with the fingers of one hand is repeated by those of the other. The patient is unable to spread the fingers of one hand, to adduct or abduct one thumb, or form one hand into a fist. Closing one eyelid is also impossible. Electrical irritation applied to the muscles of the fingers and hand of one side produces the same motions on both sides. Fuchs emphasizes the extreme rarity of this phenomenon in otherwise perfectly healthy subjects, and mentions a few cases hitherto observed. As possible causes Fuchs cites the hypotheses of other observers, such as simultaneous cerebrospinal innervation, disturbances of coördination, encephalitis in early infancy, etc. These double movements prove a great hindrance to the patient when executing more complicated movements, writing, pianoplaying, sewing, etc. It takes the patient hours to dress. Within nine months she made very little progress in learning typewriting.

Before the Scientific Association of Physicians at Innsbruck, Professor Mark presented a man, thirty years of age, who had fallen and struck the dirty floor with his head, receiving a slight abrasion of the skin just above and external to the left eyebrow. The wound did not heal, but was followed by a moderate suppuration of the lymph nodes in front of the left ear. Upon admission to the hospital the affection was diagnosed as cutaneous tuberculosis, being on the boundary line between verrucose tuberculosis and papillary lupus, with subsequent suppurative adenitis, *i. e.* a tuberculous "initial lesion" with subsequent bubo. The patient, a strong, sturdy man, showed absolutely no signs of tuberculous affection of the internal organs and the case was to be regarded as one of direct inoculation into the skin.

Dr. Rusch has successfully treated a flat, benign, epithelioma of the scalp in a patient, seventy-four years old, with radium. The tumor was as large as the palm of the hand and was situated in the exterior portion of the scalp, which was denuded of hair. At the center, the tumor had undergone spontaneous cure by cicatrization, while there was a respiginous extension of the growth along the periphery in the form of thick, slightly depressed, plate-like infiltrations. Many of these infiltrations showed superficial ulceration and numerous prominent vesicular epitheliomatous nodules. Microscopical sections showed chiefly abundant infiltration of the connective tissue with plasma cells and moderate epithelial proliferations, starting partly from the epidermis and partly from the epithelium of the hair follicles and the sebaceous glands. The treatment, which was continued for several weeks, consisted in daily irradiations of every portion of the tumor, lasting from fifteen to twenty minutes, and repeated six times. There was a moderate reactionary redness and swelling, which soon disappeared and was followed by pigmentation and scaling, with retrograde changes in the carcinomatous growth. The ulcerations were first covered with a glistening, adherent membrane; when this was cast off, a growth of new skin resulted over the ulceration. To-day the site of the tumor is covered with a tender, white, shining cicatrix. The action of radium was, however, not uniformly effective, as was shown by the appearance of secondary epithelial nodules in the scar after a few weeks. Under the microscope these showed very scant, but definitely demonstrable epithelial proliferations, starting from the hair follicles. Repeated irradiation was, therefore, deemed necessary to destroy these secondary growths.

Prof. Anton Drasche died here on August 23. Born in Lobendau, Bohemia, in 1826, he studied in Prague, Leipsic, and Vienna, graduating in 1851. He made the struggle with Asiatic cholera the subject of his graduation thesis, as well as of most of his future work. During the cholera epidemic raging in Vienna during 1855, he took charge of the cholera section at the General Hospital and did very creditable work in combating the disease. He became lecturer on internal medicine in 1858, physician-in-chief of the Rudolf Hospital in 1872, and professor extraordinary of epidemiology in 1874. He was a member of the Imperial Board of Health, and for some time of the Municipal Council of Vienna; in both these offices he used his influence to promote hygienic measures. He was a splendid teacher, a zealous investigator, and an extremely popular physician. Notwithstanding his extensive activity, he found time to devote to scientific writings. His most important works deal with Asiatic cholera, and its prevention, with questions of hygiene, with infectious diseases, and cardiac and pulmonary diseases. He also edited the large "Bibliothek der medizinischen Wissenschaften."

Progress of Medical Science.

The Boston Medical and Surgical Journal, Sept. 15, 1904.

The Gynecological Aspect of Mental Overstrain at Puberty, and Its Influence on Development.—Wm. Edgar Darnall emphasizes the great importance of the careful oversight of girls during the period of puberty which is the most critical time in the entire life of a woman. At this period the girl is most susceptible to mental, moral, and physical influences. She may unwittingly expose herself to dangers that will sap her energies throughout life. The average girl at this age is under the pressure of the modern methods of education. The physiological processes of puberty make greater demands on the girl than on the boy. Aside from the strain of school life, the home life is often badly regulated. The girl should not be given work that will overtax her in any respect. Gymnastic work should be suspended during menstruation for fear that it may bring on pelvic disease. Dysmenorrhœa is the bane of the overwrought school girl. Jane Kelley Sabine has found that 75 per cent. of 2,000 school girls suffer with menstrual troubles, and 90 per cent. with leucorrhœa and ovarian neuralgias. The mental or nervous element is a more prominent factor than is generally considered, in relation to these functions. The forced education which is so common in these days, leads to flabby muscular development, poorly developed lungs, anæmia, malnutrition, weak heart, and arteries, poor digestion, nervous irritation, chorea, hysteria, and collapse. The writer concludes his paper as follows: Not until teachers and parents remember that health is more important than knowledge; not until schools realize the futility of the forcing process of education, and guard the health of their girls by diminishing rather than increasing the work of the pubescent period, not until they appreciate more fully that a sound mind depends upon a sound body, can we hope to diminish the pitiable army of suffering neurotics and sexual incompetents, who so largely constitute the womanhood of the land, and who are to be the mothers of the men of our country.

Obstructive Renal Retention with Anuria, and Its Treatment.—Francis S. Watson discusses in this paper only those forms of renal retention with which anuria is associated, and which originate in complete closure of the ureter or of the outlet of the renal pelvis. Although it is customary to assert that the anuria seen in connection with these cases does not occur if the kidney of the other side is normal, there is evidence that this is not absolutely so. Cases are reported which ended fatally, in which the unobstructed kidney was found at post-mortem to be normal or nearly so. Further evidence has been offered that reflex suppression may exist in these cases, by observers who have cut down upon the second kidney, after an operation on the first, and have found it, to all appearance, normal. The most striking feature of obstructive anuria is the length of time it may last without giving rise to uræmic symptoms, and without causing death. In a num-

ber of cases examined, it was determined that this period varied from twenty-four hours or less to sixteen days. The most plausible explanation of the remarkable immunity to uræmic intoxication, the writer believes to be that which is afforded by assuming it to be due to the so-called "internal secretion" of the kidney. Cases in which the obstructed kidney is hydronephrotic are more hopeful than those in which hydronephrosis is not present. There are two general classes of cases: Those in which it is hard to recognize the trouble, or in which it is difficult to determine on which side the obstruction exists, and those which are easily diagnosed. The case may be treated expectantly or operatively. The following measures may be used. Subcutaneous injections of saline solution may be given. In cases of calculus obstruction, hot hip baths and manipulation to aid the passage of the stone are often helpful. Anæsthetics are sometimes used to relax the spasm of the ureter. When there is a kink in the ureter, the patient's hips should be raised, and the abdomen relaxed. In every case in which the obstruction has not been relieved by the end of the first forty-eight hours at most, operation should be performed. As to the nature of the operation, the writer declares that the essential point by surgical intervention is the reëstablishment of the urinary secretion by supplying a free avenue for the escape of the urine from the obstructed kidney by whatever operation will accomplish it most quickly and with the least shock. A quickly performed lumbar nephrotomy is without question the most suitable.

Journal of the American Medical Association, Sept. 17, 1904.

A Method of Dispensing with Rubber Gloves and the Adhesive Rubber Dam.—John B. Murphy presents his second communication on this topic. An impermeable coating, designed to prevent the escape of the epithelium and sebaceous gland secretions from the skin during operations and the entrance of blood, pus, etc., into the crevices of the skin, is made in the application of a four to eight-per-cent. solution of gutta-percha in benzine or acetone—the acetone solution for surface applications at and around the field of operation, the benzine solution for use of the hands. Experiments were reported showing the comparative results between the rubber solution and the gloves, which gave a fair idea of the comparative advantages of the rubber gloves and solution over the naked hands. Since his first report he has used the solution on his hands and on the operative field in all operations, septic and non-septic, and he is convinced that it is a simple and practical means of protection for the operator and the patient.

Boric-acid Poisoning.—Charles I. Best gives a report of a fatal case. Unfortunately the reactions of the blood and secretions were not taken. All the cardinal points of boric-acid poisoning were present, such as profuse vomiting, a papular rash over the face, neck, and chest, and a weak irregular pulse increasing before death. It differed only in its more rapid course; the onset was immediate and the fatal termination occurred in four days. The findings limited the cause of death to one of two things: a toxæmia, resulting either from the abscess in the groin or from the medicinal agent employed, as other recognizable causes were not present. Its resemblance to cases previously reported, together with the demonstrated overuse of this substance, is sufficient to make a positive diagnosis of fatal boric-acid intoxication. The clinical features and the lack of success in cultivating pathogenic bacteria from the blood, eliminate septicæmia, which is the condition most likely to simulate such an intoxication.

A Case of Cortical Hemorrhage Following Scarlet Fever.—E. E. Southard and F. R. Sims report such a case, in which they seek to bring out the predominance of hemorrhage and phagocytosis with destruction of cortical tissue, the focal effect of meningeal suppuration in a case of subinfection with the aureus during convalescence from scarlet fever. The case is one of cortical hemiplegia caught in progress, and brings out the now frequently exemplified inflammatory origin of the disease. There are several characteristics of the lesion produced in the brain by bacteria or their toxins which serve to obscure the issue by drawing attention, on the one hand, to the vascular system, and, on the other hand, to the neuroglia. Thus a recent triadic division of encephalitis into purulent, hemorrhagic, and hyperplastic, is based on the preponderance in the histological picture of suppuration, diapedesis, and hemorrhage, or secondary glia-cell changes. It is, however, probable that all these pictures may be produced by identical agents. The omnipresence of the meningeal and adventitial phagocyte has contributed a false unification of the pictures of bacterial and those of mechanical origin.

Medical News, September 17, 1904.

Treatment of Acute Middle-ear Disease.—John A. Donovan states that acute otitis occurs most often in children, and nearly always follows some irritated condition of the nasal pharynx; of these, the earliest and most common is adenoids, which should be looked for in all cases. The writer prefers the curette, finger nail, or nail curette for removing them. As to the anæsthetic, chloroform is extremely dangerous. Ether is safer, but nitrous oxide is better still. Usually, the first symptom of acute otitis is pain. In infants this is often overlooked. Many develop meningitis before it is suspected. All infants should be watched for manifest signs of earache. In adults the diagnosis is easily made. Active treatment consists in relieving pain, endeavoring to avoid suppuration, and other complications. The writer finally presents the following conclusions: (1) In all diseases affecting the nasopharynx, always use reasonable precautions to avoid tubal infections. (2) Adenoid tissue, in any amount, and tonsils producing any pathological symptoms, should always be removed. (3) With the first symptoms of earache, use heat and dehydrating remedies; this not producing beneficial results in a few hours, treat surgically. (4) When possible, with a catheter use mild continuous stream of hot air early, and repeat in eight or ten hours. (5) If symptoms are not relieved by these methods within ten to twenty-four hours, make free incision through the entire drum, or extend into upper canal wall if necessary. Use aseptic gauze drainage and outside pad for absorption. (6) Never, under any conditions, allow the patient to suffer tortures for more than forty-eight hours, and remain exposed to the risks of complications. N. B.—Considerable experience with the catheter treatment, since writing the above, fully confirms the original hopeful anticipations, and has very much lessened the number of cases requiring opening of the drum.

The Value of Early Incision of the Membrana Tympani in the Treatment of Acute Suppuration of the Middle Ear.—Francis R. Packard speaks especially of twelve cases of this nature that came under his care in the months of February and March of the present year. In the cases in which spontaneous rupture occurred, the patient suffered much pain in the ear for many days after the rupture had happened, and in two cases the discharge continued for four weeks. In the cases in which early incision was practised, there was almost instantaneous relief from pain, and the discharge had ceased in one instance at the end of three days. The plan of treatment was the same after the drum membrane had been opened, whether spontaneously or with the knife. The writer describes it as follows: It consisted in a thorough cleansing of the ear once daily by mopping out with peroxide of hydrogen, full strength, applied on cotton pledgets, followed when the discharge was very profuse by injecting a few small syringes full of bichloride of mercury 1 to 4,000 solution. After thoroughly drying, a wick of iodoform gauze was introduced throughout the whole length of the canal, and left in position until the next day, the nurse or patient being given instructions to remove it if there were any evidence of it damming up the pus. The writer believes that drainage by this method is the most efficient means of avoiding stagnation of the discharge, pain, and mastoid involvement. In cases of great pain, comfort was afforded the patient, if after cleansing the ear and drying it, an anæsthetic mixture consisting of five parts of a ten-per-cent. solution of cocaine, combined with fifty parts of anilin oil, and fifty parts of 5 per cent. of alcohol was instilled. This was allowed to remain in the ear for a few minutes, and mopped out before the insertion of the gauze drain. But as a case of death has been reported from the use of this mixture, it should be employed with great caution. The writer emphasizes the following points in the treatment of acute suppurative otitis media: First, the great value of early incision of the membrana tympani. Second, the many advantages possessed by the so-called dry treatment, and by practising efficient gauze drainage. He believes that douching out the ear by the patient or nurse is distinctly contraindicated from the fact that no one but a skilled aurist can properly dry the ear after such procedures, and that the little pool of fluid which is left is very harmful in that it affords moisture for the furtherance of bacterial growth.

New York Medical Journal, September 17, 1904.

The Susceptibility of the New-born to Measles.—Edwin E. Graham reports a case showing the non-susceptibility to measles of an infant at full term. He calls attention to an epidemic of 107 cases of measles occurring at the Infants' and Children's Hospital, Randall's Island, of which 25, or 23.36 per cent, were one year of age or less. Of these 25, four were six months of age or less. This would tend to show that six months seems to be the age at which distinct susceptibility to the disease begins.

Elevation of the Hips in the Treatment of Placenta Prævia.—Alfred King reports a case of marginal attach-

ment of the placenta, with os patulous and beginning to dilate, and head presenting. The patient was placed in the lithotomy position at the edge of the bed, and then the castors were removed. The side of the bed to which the patient was brought, was elevated and held so by means of two wooden chairs placed under the legs of that side. The plane of the patient's body was now about an angle of forty-five degrees with the floor, and the axes of the pelvic planes were more nearly horizontal Gravity, by preventing the loss of blood and the escape of the amniotic fluid, and by causing the fœtus to settle to the fundus, facilitated turning as well as speedy and safe delivery. The time occupied was not over five minutes. The loss of blood was very slight, not an ounce.

Post-mortem Examinations for Medicolegal Purposes.—I. L. Polozker, after telling the purposes for which post-mortems are held, describes the proper conduct of such examinations, especially for medicolegal purposes. He asks why men should be allowed to go on the witness-stand and pose as experts on subjects that are foreign to them. This is what kills medical expert testimony. Medical men, he says, often have the bad habit of giving an opinion offhand. He claims that the existing conditions can be remedied by having the local society go before the legislature, and demand better laws governing medical testimony. A board of medical experts should be appointed by the court and on the recommendation of the local medical society. The coroner's court should be abolished; this he believes to be simply a drain upon the county. Instead, the prosecuting attorney should appoint a physician to investigate sudden deaths. The board of supervisors should be asked to make an appropriation for the erection of a suitable building for a county morgue, where satisfactory work could be done by county physicians. Post-mortem work should be better taught in our medical colleges, and the only satisfactory way is by demonstrations in the dead house.

Tracoma and Some Diseases Resembling It.—James N. Nydegger states that papillary conjunctivitis, or enlargement of the papillæ of the conjunctiva, is frequently mistaken for trachoma. Upon everting the lid, the hypertrophied papillæ may be seen set closely together and giving the appearance of fine grained sandpaper. This condition is more often seen in eyes having high refractive errors or muscular insufficiencies, and is not to be associated with trachoma. There is little or no thickening of the conjunctiva in follicular conjunctivitis and no traces are left behind after recovery. In the incipient stage the two diseases are difficult to distinguish from each other. Trachoma follicles are to be regarded as new tissue. The follicles, granules, granulations, or nodes—these terms are used interchangeably—form the characteristic picture of trachoma. They are the result of inflammation and show first as a fine net of capillaries with fine partitions. These granulations lie in the adenoid structure of the conjunctiva and extend or arch the epithelium before them The conjunctiva presents a thickened, soft velvety appearance. Trachoma follicles develop first, principally on the lower lid. If one turns back the upper lid, the granulations almost always cease with a sharp horizontal line over the upper border of the tarsal cartilage, in the region of the anterior margin of the retrotarsal fold. The outcome of trachoma granulations may be a discharge of the contents or resorption of the contents; in both ways the cicatrices close. In trachoma there is always found an inflammation of the mucous membrane which surround the follicles, and a reaction is always produced. The late and serious complication of trachoma are pannus and atrophy of the cornea, the latter being due to mechanical pressure of the contracted lids. The former is due to the constant pressure exerted upon the anterior part of the eye by the thickened and contracted conjunctiva which interferes with the nutrition of the cornea, and degenerative changes follow. Trachoma is, without doubt, due to a specific organism which has not been convincingly demonstrated.

American Medicine, September 17, 1904.

Intermittent Lameness and Other Nervous Symptoms of Peripheral Arterial Disease.—Charles W. Burr states that the best known, and the most studied nervous effect of peripheral obliterating arteritis is intermittent lameness. Erb calls this affection dysbasia angiosclerotica. There is quite a little variability in the symptomatology, but the writer describes the course of events in a typical case as follows: The patient, while walking, is seized with pain or numbness, localized or diffuse, in one or both legs, and at the same time there is a feeling of stiffness, or even distinct cramp, in the calves or thighs. If the patient sits down relief comes quickly, but very soon after beginning to walk again the symptoms return, and soon he is unable to walk at all, not only on account of pain, but also because of muscular disability. If now the patient be examined, the arteries in the feet, and it may be even the femorals, will be found pulseless, the arterial walls will be felt to be distinctly thickened, and the feet may be warm, cold, or normal in temperature, and red, or cyanosed, or natural in color. The most striking thing is the absence of the pulse in the member or members affected. The duration of an attack varies from minutes to hours. They come on almost always during muscular exertion. The legs are much more frequently affected than the arms. Very rarely, as in a case reported, the arm and leg of the same side are seized almost simultaneously, producing a condition superficially resembling a transient cerebral hemiplegia. Occasionally only one arm is affected It is very rare under forty, and is much more common in men than in women. The writer then gives the history of a fatal case in which gangrene developed. Glycosuria is a frequent complication in both slight and severe cases. The one constant symptom in intermittent lameness is chronic arteritis. The chronic non-paroxysmal manifestations of chronic general arterial sclerosis appear with the oncoming of old age, whether the man be young or old in years.

Eyestrain as a Causative Factor in Sinusitis.—William Linton Phillips, although he does not think that all forms of accessory sinusitis are due to eyestrain, still believes that eyestrain holds an important place in the production and maintenance of this condition. In making a diagnosis of frontal sinusitis, the first fact to be ascertained is at what early age the frontal sinuses develop, for they are not present at birth. Observations in relation to this question show that we can and must look for the sinus as early as the sixth year of life. Nationality must also be regarded. In the German, the sinus attains a greater development, other nations coming in the following order: Irish, Swiss, North-American Indian, British, French, Greek, Egyptian, Peruvian; the Russians, Poles, and Eskimos collectively; then the negro and Chinese. Patients who suffer with frontal sinusitis complain of frontal headaches, pressure above the eyes, inability to concentrate the mind, occipital headache, dizziness, and nausea. Associated with these symptoms are defective vision, infection of the conjunctiva, swelling and redness of the skin over the cavity, œdema of the upper lid, tenderness above and beneath the supraorbital ridge, and painful sensations in the back part of the eye. The only way to make a positive diagnosis is first to establish the presence of pus within the cavity. This, however, is difficult to accomplish. Care must be taken while diagnosing frontal disease to exclude supraorbital neuralgia on account of its almost latent course. In cases of doubtful diagnosis between frontal sinusitis, meningocele, and aneurysm of the ophthalmic artery, it is well to draw off some of the fluid for microscopical examination. The writer declares that to produce clear vision with an astigmatic eye we must use up all of the residual nerve energy, because of the increased work required to focus an eye that has different meridianal lengths. This drain of nerve force robs other parts of the required energy to keep up a normal condition, and acts as would a division of the vasomotor nerves dilating the blood-vessels and increasing the amount of mucus in the frontal sinus. If this secretion is allowed to accumulate from day to day it will eventually become infected by germs entering the sinus from the nasal cavity, which may be forced upward by the act of blowing the nose, etc. The writer concludes his paper by giving the history of a series of cases. He did not use or allow to be used any treatment for the relief of frontal sinusitis, other than glasses, but he adds that he advises that the condition should be treated locally, in addition to correction of any eyestrain which may be present.

The Lancet, September 10, 1904.

Tender Spots on the Spine in Relation to Pain in Various Parts of the Body.—St. Clair B. Shadwell wishes to emphasize the fact that pain is often felt at a distance from the actual seat of the disease, and he reports several cases in which he has found well-marked tender spots at the point of origin of the spinal nerves supplying the region of the body in which pain is complained of, and by treating the tender spots on the spine complete, immediate, and permanent relief has been the result.

A Case of Pseudoleukæmia (Lymphosarcoma) in a Young Child.—John J. Redfern reports such a case which is of interest both on account of its acuteness and the early age at which it occurred. The patient was a healthy, plump, well-developed little girl, two years and nine months old, with several swollen glands on the left side of the neck and some less swollen on the right side. These glands were firm, discrete, and somewhat elastic, not painful or tender on pressure. The case terminated fatally by syncope after about eight weeks' illness. The disease had progressed rapidly, although the child's general condition

had remained good. The usual œdema and pallor were not very marked and the general nutrition of the body was maintained until death. The spleen and liver were not markedly enlarged on percussion. There was no pain or cough. Pyrexia was intermittent and under 101° F. Arsenic was administered throughout and at first iodide of iron and cod-liver oil. There was no family history of syphilis or tuberculosis.

The Treatment of Rectal Prolapse by the Submucous Injection of Paraffin.—Arthur H. Burgess, during the past eighteen months, has utilized this method in eighteen cases of prolapsus recti. Following a description of the technique he gives his results. Of the eighteen cases the ages ranged from three to forty-eight years and the prolapse from one and a half to five inches in length. The result of the operation has been extremely satisfactory in all the cases, not a single instance of re-descent of the prolapse having occurred. Two possible dangers that suggest themselves are those of sepsis and of pulmonary embolism. He recently had an opportunity of making a post-mortem examination in the case of a boy upon whom he had operated four and a half months after the operation. The masses of paraffin did not appear to have undergone any material change; they were firmly encapsulated by fibrous tissue, which had also infiltrated their peripheral portions for a slight distance, but for the main part they consisted of unaltered paraffin. The paraffin had remained strictly localized to the area of introduction.

Human Piroplasmosis.—C. Donovan, after a year's experience of the disease caused by the sporozoan parasite, classified by Laveran and Mesnil in the genus pirplasma, during which time seventy-two cases diagnosed by examination of the blood from splenic puncture came under his notice, describes the disease. It is especially prevalent in the unsanitary parts of Madras. The sexes are equally amenable and age is no bar to the affection. He noticed many cases of chronic irregular pyrexia with enlargement of the spleen, and occasionally of the liver; bronchitis, œdema of the feet, subcutaneous hemorrhages, chiefly of the petechial type; diarrhœa of the dysenteric type, and cancrum oris. Not being satisfied with the diagnosis of chronic malaria he took smears of blood from the spleens at several post-mortems in cases said to have died from chronic malaria. The slides showed numerous peculiar round and oval ring-like little bodies, with two masses of chromatin situated on opposite poles; but unlike any known group of protozoa. Later he punctured the spleen of a living boy affected with the disease and found the same forms larger, more varied in appearance and more clearly defined. Major W. B. Leishman had found the same organisms but called them degenerations of trypanozomata. After sending specimens to Ross and Mesnil it was decided that the bodies belonged to the genus piroplasma but were a new species, to whichthey gave the name *piroplasma Donovani*. Blood specimens taken from cases of kala-azar showed that his surmise that these so-called malarial cases in Madras were identical with these diseases was correct. From the date of first finding the piroplasma, he practised this small operation in all cases suffering from irregular pyrexia and enlargement of the spleen. One hundred and ten punctures have been made; the cases in which piroplasma was not found contained either the gametes of the latent forms of the genera plasmodium and laverania; in others no recognized organism was detected. The number of organisms in the blood taken by splenic puncture during life varied from one to thirty or more in the field. The number, although varying with the amount of blood taken up in the syringe, is not dependent upon the severity or otherwise of the disease or the size of the spleen.

British Medical Journal, September 10, 1904.

Preliminary Report of Some Investigations into the Etiology of Leukæmia.—T. Gillman Moorhead has carried out a series of experiments with a supply of glands obtained post mortem from a patient who had suffered from the lymphatic form of this disease. Blood-pressure experiments were made on full-grown rabbits, in the first instance. Later experiments were performed upon young rabbits, consisting in the hypodermic injection of extracts. The writer presents the following tentative conclusions, which he states that future investigation may either establish or overthrow: (1) After precipitation with alcohol, a substance can be extracted from leukæmia lymph glands by saline solution, which produces a marked fall of blood pressure in rabbits. This depressor substance is not a constituent of ordinary lymphoid tissue, inasmuch as similar extracts of normal lymph glands and of thymus glands do not contain it. (2) The above-mentioned depressor substance is possibly a specific toxin, because continuous injection of the extract containing it produced marked changes in the hæmopoietic tissues in rabbits. It is to be noted that these changes were not confined to any one of these tissues, but involved them all. The rapid development of changes may be supposed to be due to the large quantities of toxin which were injected on each occasion.

Immunity.—Robert Muir first discusses the nature of the combination of antisubstances. In the case of natural lysins, there are striking variations in the combining affinities. In the guinea-pig's serum, for example, there is a natural immune body which has a great affinity for ox's corpuscles, so that it can be readily removed from the serum by contact with the ox's corpuscles. In the case of the natural immune body of the guinea-pig's serum for rabbit's corpuscles and that of the rabbit's serum for guinea-pig's corpuscles, the combining affinity is much less, and when the serum is left in contact with even a great excess of corpuscles, a considerable amount of the immune body still remains free. It is important to note that the combining affinities of the natural homologues of immune body vary so much, and that they are on the whole weaker than is the case with an artificially produced immune serum. As to the saturation phenomena, when immune body is added to red corpuscles, the amount which enters into combination is not a fixed quantity, but varies according to the amount of immune body present. It is an example of mass action. The combination of the receptors with immune body is a reversible action. In relation to the subject of complements, the writer declares that the intact corpuscles, even when treated with immune body, are almost impervious to complementoid, whereas after the toxic action of complement has occurred, complementoid readily enters into combination. This is a new fact in regard to the combination of such substances. The existence of complementoid—that is, complement modified by heat—has been completely proved. After various investigations the writer believes that, in order that a bactericidal serum be efficient therapeutically, not only must the complement concerned combine readily through the medium of the immune body, but the bacterium must be sensitive to the action of the zymotoxic group of the complement. As to the combining affinities of receptor, immune body, and complement, the writer states that two molecules receptor and immune body are each incapable of taking up complement when separate, but do so when combined; in a certain sense one of these two molecules sensitizes the other to the combining affinity of the complement. The writer concludes by saying that in the discussion of this subject, he makes no dogmatic assertions, as he considers that at present no conclusions can be considered as completely proved.

Nature, Relations, Origin, and Function of Lymphocytes.—G. Lovell Gulland gives as his view that the lymphocytes, mononuclears, and transitionals are merely stages in the development of one type, and that there is no relation between the transitionals and the polymorphonuclear neutrophiles. He believes that the small and large lymphocytes, mononuclears, and transitionals should all be regarded as belonging to one series, and the last two names should be allowed to drop out of use, except with the understanding that they are used as applied to lymphocytes. The writer regards leucocytes as classifiable in four series—lymphocyte, neutrophile, eosinophile, and basophile or mast cells. In the other series, the cells pass through the same cycle of changes as in the lymphocyte series, with this difference that in them only the terminal or polymorphonuclear stage is found in the blood under normal conditions, while all the members of the lymphocyte series are found normally in the blood. The terminal form (transitionals) of the lymphocyte series is rare in blood, glands, or marrow. Clinically and experimentally, in adult life, the various series are different, and react differently to different stimuli. As to the theory that erythroblasts are derived from lymphocytes, the author declares that there must have been in an embryo rabbit, which he has recently studied, some thousands of erythroblasts to one lymphocyte, and in later life he believes that there is just as little question of a transition. As to the origin of the lymphocytes, no one doubts their formation in lymph-glands, and in the lymphatic tissue of the tonsils, intestines, spleen, etc. The writer believes that there are enormous numbers of lymphocytes of all kinds in the marrow. Experiments as yet unpublished have confirmed the view that they are mainly derived from the marrow. The function of these cells is doubtless largely protective. It is not yet settled whether those of the blood are directly protective. Aside from the lymph-glands and marrow, the main depots of lymphocytes are round the hollow tubes of the body, the alimentary and respiratory tracts, and these are the places which are occupied by sapophytic, non-virulent, or attenuated organisms. It seems possible that the lymphocytes are adapted and sufficient to resist such microorganisms but not sufficient to resist virulent infections which have to be overcome by the polymorphonuclears.

Book Reviews.

Transactions of the American Roentgen Ray Society. Fourth Annual Meeting, Philadelphia, Pa., December 9 and 10, 1903. Murdoch-Kerr Press, 1904.

The society is to be congratulated upon the vigor of its infancy as indicated by the present report. This is one of the few societies that can be counted upon to offer an excess of strictly new matter at its yearly meetings. The report has been carefully prepared and contains much of interest and, at the same time, not a little of what will one day be known as nonsense.

Arteria Uterina Ovarica, or the Genital Vascular Circle. By Byron Robinson, B.S., M.D., of Chicago. Chicago: E. H. Colegrove, 1903.

In this book Dr. Robinson devotes himself to a complete description, embellished by over one hundred illustrations, of the utero-ovarian artery and the cricle of genital blood vessels with which his name is associated. The circle, which he claims has far more utility in medicine than the circle of Willis, consists of the uterine-ovarian artery, with part of the abdominal aorta, common iliac, and internal iliac. New features presented in this work include the supposed utility of this genital vascular circle in surgical interventions on the genital tract, and also the fact that on account of the mobility and capacity for extension of the genital vascular circle, the internal genitals may pass up to the diaphragm (as in pregnancy) or be drawn through the vulvar outlet for purposes of inspection or repair, without loss of integrity. For the purpose of defunctionating the genital tract as regards reproduction and menstruation, without ablation of organs or ligation of arteries, the author presents the operation of endometrectomy and partial myomectomy, conducted through the vagina. The uterus is drawn down and the bladder and rectum separated through incisions in the anterior and posterior vaginal fornices. The middle section of the uterus may then be removed with the scissors and the anterior and posterior edges of the cut tissues sutured, thus closing in all uterine tissue. He claims to have had good success with this procedure for two years. There is little hemorrhage if the suturing be done as the uterus is cut. The segments atrophy and no neurotic menopause arises. The subject treated in this work has received very scant attention by the anatomists, only four publications being known.

Unconscious Therapeutics; or, The Personality of the Physician. By Alfred Schofield, M.D., M.R.C.S., etc., Hon. Physician to Friedenheim Hospital, Author of "The Unconscious Mind," "The Force of Mind," etc. Philadelphia: P. Blakiston's Son & Co., 1904.

The literature on psychotherapy within the ranks of the profession is very scanty, and considering how this branch of treatment has been largely relegated to irregular practitioners, quacks, and charlatans the necessity for good books upon it is very pressing, and perhaps never quite so much so as at the present day, when Eddyism, osteopathy, the new thought, and numerous other methods of healing, in which the personal element plays an important rôle, are flaunted over the land. Dr. Schofield's book affords a very satisfactory insight into the possibilities of "unconscious therapeutics," and makes it plain to those with doubting minds that this branch of the healing art is both ethical and legitimate. Once it is decided that there is a power for good in "unconscious therapeutics," and, as the author well states, few are hardy enough to deny it, the natural conclusion must be that no medical training can be complete that does not teach it. Aside from desultory lectures, no systematic attempt has ever been made to instruct the medical student in this subject, and in practice it may be a difficult matter to do so, but the author's suggestions are nevertheless worthy of attention. Amongst others the curriculum might embrace the following subjects: (1) The general facts connected with the unity of man and the interdependence of the psychic and physical in all parts of the body, and in all the different organs. (2) Another subject might be that of temperaments, mental conditions compatible with sanity, nervous states and phases, etc. (3) Different characters might be studied and the way in which education, reasoning, or emotional powers aided or retarded the action of unconscious therapeutics. (4) A study of the psychic, as distinguished from the physical action of drugs. (5) All forms of suggestion, direct and indirect, plain or wrapped up in various treatments, which might be made to include various forms of autosuggestion and hypnotism. (7) Lastly, a careful consideration of the personality of the physician—ethics, morals, professional conduct and etiquette, tact, dress, manners, and general surroundings. The book is written in a most entertaining fashion and merits the attention of young men starting out in practice, and perhaps may help some of those in whom a lack of success may be traced to some of the factors described by the author.

Tenement-house Inspection. By George M. Price, M.D. New York, The Chief Publishing Co., 1904.

This book is written expressly for candidates for the Civil Service position of Inspector in the Tenement-house Department of the City of New York, although it will prove of value to tenement-house owners and dwellers who would be benefited by a closer acquaintance with legislation and sanitation applying to this class of dwellings. The author is well qualified for the task by the fact that he has been connected in an official capacity with these departments of the city government for a number of years. The book contains chapters on the tenement-house law and the building construction, ventilation, and plumbing in these dwellings. Tenement inspection is treated in a concise but clear manner, and the subject of civil-service examination is very completely discussed. The latter will prove a boon to intending candidates, as nothing else on this subject has thus far been published. A full text of the Tenement House Act completes this valuable little manual.

Appletons' Medical Dictionary. An Illustrated Dictionary of Medicine and Allied Subjects, in which are given the Derivation, Accentuation, and Definition of Terms Used Throughout the Entire Field of Medical Science. Edited by Frank P. Foster, M.D., Editor of the *New York Medical Journal and Philadelphia Medical Journal, Consolidated*; of a Reference Book of Practical Therapeutics, and of Foster's Illustrated Encyclopædic Medical Dictionary. New York and London: D. Appleton & Company, 1904.

To the possessor of the four bulky volumes of Foster's Encyclopædic Dictionary who has remained attached to that great work despite its increasing age, because of the convenience of its arrangement and the clearness and simplicity of its definitions, the announcement of a one-volume dictionary by the same editor will be welcome news. This volume is large, very large, nearly two thousand pages, but it is a single volume, and so its size can be forgiven. As a dictionary the work has many excellencies. The pronunciation is, as a rule, indicated only by accenting the title-words, the derivations are given briefly, and the French and German equivalents, and often the Greek, are inserted when they differ materially from the English. In regard to orthography, we are glad to see that Dr. Foster does not favor what he calls "the fad of substituting the termination *-ic* for *-ical*, dispensing with the final *e* in such terminations as *-ine* and *-ide*, and suppressing diphthongs." The definitions are clear and concise and, so far as we have been able to discover, accurate. In fine, the only serious criticism of the work is its size, which might have been reduced by a careful pruning and rejection of obsolete words; but this counts for little in view of the convenience of arrangement, the accuracy of definition, the completeness, and the beauty of typography and binding.

A System of Practical Surgery. By Profs. v. Bergmann, v. Bruns, and v. Mickulicz. Vol. III, Surgery of the Extremities. Edited and translated by Drs. Wm. T. Bull and J. B. Solley. New York and Philadelphia: Lea Brothers & Co., 1904.

The American edition of this great German work is now being rapidly completed, and the third of the five volumes to be issued has appeared. It deals with the surgery of the extremities, and the contributors are Borchardt, Friedrich, Hoffa, Hofmeister, Nasse, Reichel, Schreiber, and Wilms—all well known in their special lines of endeavor. The first section, by Hofmeister and Schreiber, deals with the malformations, diseases, and injuries of the upper arm and shoulder; the second, by Wilms, considers the same conditions in the elbow and forearm; the third, by Friedrich, the wrist and hand; the fourth, by Hoffa, the hip and thigh; the fifth, by Reichel, the knee and leg; the sixth, by Nasse and Borchardt, the ankle and foot. All these are discussed in considerable detail, but the most elaborate section is that contributed by Hoffa, and this will attract the most attention on account of the position of the author in the field of orthopedic surgery. Congenital dislocation of the hip-joint being one of the topics of the day is very fully treated. Hoffa believes that the Lorenz method is applicable only within certain limitations, and thinks that the only operation to be considered at the present time is the open reduction of the dislocated head into the enlarged old cavity, which he describes under the caption of the Hoffa-Lorenz operation. The other sections of the book are sufficiently complete to make the work an excellent manual of reference. The illustrations derived from the German edition are, as a rule, very poor, but those introduced by the American editors are good, and although not referred to specifically in the text, still serve to add interest to the latter. Those contributed by one of the translators, Dr. Solley, are particularly appropriate and well executed.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held May 12, 1904.

DR. MATTHIAS NICOLL, CHAIRMAN, PRO TEM.

Demonstration of a Pasteurizer, Sterilizer, and Infant's Nursing Bottle-holder.—Dr. THERON W. KILMER, after stating the dangers of improperly prepared bottles and milk, presented an apparatus which, in his hands, had proven effective and which consisted simply in a pail and bottle-holder. There were two bottle-holders, one for ten six-ounce bottles and another for seven eight-ounce bottles, and each fitted in the same rack in the same pail. Having introduced the bottle-holder and bottles in the rack, the pail was partly filled with water and covered. When the operation was completed, instead of touching the bottles with the dirty hands or a dirty towel, one simply took the pail to the sink and turned the pail upside down and allowed the bottles to drain dry.

If one wished to sterilize milk, the bottles should be filled and placed in the holder and in the pail; then the pail should be partly filled with water and placed on the stove and the water boiled for a certain length of time; then the milk should be gradually cooled and placed on ice.

If one wish to Pasteurize the milk, the Pasteurizing temperature being from 158 to 165°, the cold bottle containing milk at 50° was plunged into boiling water at 212°. If the bottles have been previously boiled they become so annealed that breaking of bottles by suddenly thrusting them in boiling water did not occur. If one wished to travel with a bottle-fed baby the apparatus presented was very convenient. After preparing a number of bottles of milk, the pail could be used as an ice-box by packing ice around the bottles.

Cerebrospinal Meningitis.—Dr. WM. P. NORTHRUP gave his experiences with this disease during the epidemic, which began March 1. The first case that he saw on that date was fortunate, a typical one, and a diagnosis was readily made. This disease was a disease of young adult life and children. His youngest patient was five months old and his oldest twenty-three years old. He referred to two boys who were playing ball in a particular lot and who became very much heated and partook of cold drinks; shortly after, both were seized with violent delirium and all the symptoms of a severe case of cerebrospinal meningitis. One boy recovered, the other died. On the same day he was called to see a girl who, two weeks before, was at a dance, became over-heated, had cold drinks, and she was taken down with the disease. A report of several other cases was made, and he presented a composite picture of these cases, some having prodromes of general malaise for from a few hours to two days; then appeared the symptoms of pain, headache, fever, vomiting, rigidity of the neck, opisthotonus, the eruptions of petechiæ (fleabites) and delirium, somnolence, Kernig's sign, general hyperæsthesia very well marked, the peculiar attitude well described by French writers as the "gun hammer" position. There was also arrhythmia and cardiac slowness. Dr. Northrup said he was at sea when attempting to give a prognosis—in fact, he felt he could not make one, and when asked for one usually he evaded answering. Lumbar puncture seemed to aid in diagnosis only. He asked what did good in the way of treatment? His own plan was to use a combination of bromides, 30 grains, chloral hydrate, 10 grains, and opium, ¼ of a grain. He said the mortality varied in different epidemics, and what it would be in the present one he could not say. These epidemics, as a rule, followed prolonged and severe winters, which kept the people shut up. Recently he had met an army officer from Alaska, where there was an epidemic of this disease, and it seemed strange that most all the cases occurred among the packers, *i.e.* those who carried packs through the mountain passes, who lived out doors, with plenty of ventilation and exercise. He wondered why they should have it. This was an epidemic disease, but he did not think the disease was contagious.

Dr. HENRY KOPLIK said that all the cases he had seen had been quite characteristic and offered few difficulties in diagnosis. In the majority of the cases the diplococcus cellulosus was found by lumbar puncture. He believed that with the exercise of ordinary care the average physician could make a diagnosis of cerebrospinal meningitis in any given case. Yet, there were cases that one might see later in the course of the disease which were not so characteristic. Several of these cases he had met with in the wards of the hospital and occurred among children under two and a half years old, and especially in very young nurslings—as young as five months of age. In these young breast-fed infants the onset of the disease was hardly noticed by the mother because, as a rule, she was too busy with her work. Suddenly the child would have convulsions and this was quite commonly noticed. The child would have these convulsions and run temperatures for weeks without special symptoms, *i.e.* typical symptoms. In such cases the study of the temperature and the course of the disease gave no hint as to what was going on. The child would appear quite well between the rises of temperature. He had seen such cases examined carefully for otitis media and the blood examined for the plasmodium malariæ. He could not forget the cases in the wards in which nothing could be found that was positive in the diagnostic way. In 5 per cent. of the cases no history could be obtained of the child having been taken ill suddenly. The child would be watched for several days, and then it would be suggested that the child had cerebrospinal meningitis. Such cases were not at all infrequent, especially during the course of an epidemic. He had seen in his office two cases giving symptoms of a tonsillitis, with temperature and much irritability. These represented a certain type of cases, but there were other cases met with abroad, and talked of especially in London. They were very obstinate cases and began in a rather indefinite way, at times with convulsions and high febrile movement; then the child would not take note of its surroundings and would gradually pass into a condition of opisthotonus. Such cases formerly were thought to be cases of tuberculosis because, after one week, the temperature would drop and would not extend again above 101°, and the child would become hydrocephalic. With regard to lumbar puncture, he could not say that he had ever cured a case by the adoption of this measure, but he had made the patients more comfortable and prevented complications by its employment. In young infants and children the mortality, he said, was very high, and death resulted not only from sepsis but also from the effects of pressure. One of the most serious complications one met with was hydrocephalus; many children seen with enormous head will give a history of having had, during the early months of life, cerebrospinal meningitis. Therefore, lumbar puncture he believed to do a great deal to prevent complications, especially when the child was comatose, with a high temperature range, etc., because of the constant pressure from fluids. In the older children lumbar puncture would relieve the headache and drain off some of the purulent fluid and so prevent absorption. The question of injecting antiseptic fluids into the canal he believed should be discussed. He had never done it in children for two reasons: (1) the mortality was not higher than 40 per cent. when no injection was given, but higher if given; (2) the withdrawal of a certain amount of fluid and the re-injection of an antiseptic seemed to cause some disturbance which might do harm in these cases.

Dr. HENRY HEIMAN said that pressure was the cause of many of the fatal cases and, therefore, lumbar puncture seemed to be indicated, especially in the presence of cloudy fluid. The clearing up of this cloudiness was an indication that the patient was improving.

Dr. E. LIBMAN said that the bacteriology of these cases

of cerebrospinal meningitis differed to-day from cases seen five or six years ago; they were easier of cultivation and more accurate results were obtained. In getting data for statistical purposes he did not think we should include those cases seen in different epidemics because they differed so under different forms of treatment.

Dr. Koplik said that the mortalities in different epidemics ranged from 25 per cent. to 90 per cent., irrespective of any treatment given. He did not think we should say that because the mortality was great in one epidemic that this was the general mortality. He thought the present mortality was about 40 per cent. lower than in preceding years.

Dr. Charles E. Nammack said that among the first twenty-seven cases of cerebrospinal meningitis seen at Bellevue Hospital twenty-four had died; eleven of these were in children and ten of them died, and it certainly meant that this was a very fatal epidemic. Every patient he had seen personally had died. He reported the case of an Italian, seventeen years old, whom he expected to see die within forty-eight hours. Lumbar puncture brought forth pure pus, and an injection of lysol (15 c.c.) was made, with amelioration of the symptoms but with a return of them within twenty-four hours and with great severity. A second injection of the same strength was given and again with benefit. The second lumbar puncture produced purulent fluid and the third pure serum. Another injection was given, and the patient left the hospital in very good condition except that he had a sciatic neuritis. This case he reported as being one in favor of the lysol treatment. The next three patients all left the hospital by way of the morgue, and in two he succeeded in obtaining autopsies. In one it was a pure case of cerebrospinal meningitis. In the other there was a lobar pneumonia an acute ulcerative endocarditis, an old fibroid and chronic endocarditis, a calculus, a pyonephritis of one kidney, and, therefore, he should have died. The third case was a fulminant one and autopsy was refused. The patient had an intense endocarditis. To-day there were at least two cases in the wards that he thought would recover, and each was receiving the lumbar puncture and lysol injection treatment. He thought we should not feel discouraged because we could save only 40 per cent. of the cases.

Dr. William P. Northrup closed the discussion and attempted to demonstrate by means of a drawing on the black-board that frequent washings of the spinal canal could not wash away the greenish-yellow deposits that extended down into the sulci of the cord and elsewhere. By making a puncture well down in the cord he did not believe one could get rid of the material situated high up; such a method would not result in getting that thick greenish-yellow pus situated in the layers of the pia mater. When speaking of lumbar puncture, he asked that this be kept in mind, the futility of attempting, by this means, to remove this material which was so deeply situated in the layers of the pia. Lumbar puncture he believed was only good for making diagnoses and for hospital reports. That was his candid opinion.

The Action of Modern Small-bore Bullets.—Scharf (*Der Militararzt*) states that a shot from a Männlicher rifle, discharged at from two to ten meters' distance, resulted in three deaths, two mortal wounds, and seven severe or slight wounds. A skull wound, passing from the region of the right orbit to the right occipital region, showed interesting features. The wound of exit was considerably larger than the wound of entrance, but the vault of the skull was fissured both at the entrance and exit. The cause of the fracture is discussed as to whether they were due to the "hydrodynamic action" of the close shot (von Bergmann's theory) or to "fracture by irradiation" (Aran's theory). The writer advances reasons in favor of the second theory.

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY.

Tenth Annual Meeting, Held in Chicago, May 30 and 31, and June 1, 1904.

The society met in the Banquet Hall of the Auditorium Hotel, under the presidency of Dr. Norval H. Pierce of Chicago. Dr. Frank Billings of Chicago delivered an Address of Welcome.

President's Address.—The President, Dr. Norval H. Pierce, in his address, pointed out the great changes that had been wrought in the special domain of laryngology, rhinology, and otology during the life of the society. Ten years ago it was hardly more than a matter of sprays and spurs, of snares and syringes. The members no longer confined themselves to intralaryngeal, intranasal or intracranial operations, but by most radical external surgical procedures it was the aim to cure the most extensive diseases of the nose and accessory sinuses, the larynx, the pharynx, the ear, and neighboring parts within the cranial cavity. This change had taken place gradually. It took years to endeavor to set the bounds of laryngoscopy, rhinoscopy, and otoscopy. Latterly, by the work of Killian, Jensen, and of many of the Fellows, the advance had been made more rapidly, so that at the present time the well-rounded and successful specialist must not only possess that special skill and dexterity which enabled him to examine successfully the larynx, the nose, with the orifices of the several accessory sinuses, the ear, both by otoscopy and by means of complex functional tests, but he must combine with this a broad surgical knowledge equal to that of the general surgeon, and an ever-accessible knowledge of regional anatomy superior thereto. Thus did they prove the right to exist as specialists and members of the surgical department of the great science and art of medicine; but he expressed the fear that the pendulum might swing too far in the direction toward radicalism. With the technique of external operations firmly within grasp, were not the members liable to resort to them prematurely —to forget that much might be done by more conservative local measures, etc.

Some Points in the Pathology of Bone Cysts in the Accessory Sinuses of the Nose.—Dr. A. Logan Turner of Edinburgh, Scotland, by invitation, read a paper on this subject. An analysis of the various published cases illustrating this condition revealed the interesting fact that in some the bony cavity merely contained air, in others the contents were of a mucoid character, while in a third group of cases pus or mucopus was found.

Purulent Otitis Media Complicating Typhoid Fever.—Dr. Ewing W. Day of Pittsburg, Pa., read an exhaustive paper on this subject, in which he considered deafness, otitis externa, disorder of the perceptive apparatus, acute catarrhal otitis media, myringitis, and acute purulent otitis media as complications of typhoid fever.

Chronic Otitis Media.—Dr. James F. McKernon of New York reported a case of chronic otitis media, complicated by chronic mastoiditis and jugular bulb thrombosis, with operation and death. The patient, a boy of five, had scarlatina seven months previously, with a discharge from both ears. One ear ceased running after six weeks; the other continued to discharge intermittently. During the periods of intermission the child was peevish, drowsy, and constipated; the tongue coated; the breath foul. There were headache and earache. While the ear discharged, the patient's condition was approximately normal. Three weeks after the ears became affected there was pain behind both ears, worse on the right side, for ten days. On examination the right canal was found red, excoriated, and filled with foul, thick discharge. The drum was perforated over the Eustachian orifice, and in the posterior-superior quadrant; granulations and dead bone were discovered. The left drum had healed. A diagnosis of intratympanic caries was made and operation advised, but refused,

although the dangers of delay were pointed out. Under the usual palliative treatment the discharge stopped for a time, but recurred. About two months later the condition within the ear was found somewhat better. Operation was again urged, but was declined as before. Three months later the discharge increased again, and operation was agreed to. Examination at this time failed to reveal any signs of mastoid trouble, but the general physical condition was not so good. Temperature, 99° F. When the mastoid was opened the cortex was dark; the antrum, tip, zygomatic root, and several medullary spaces behind the sigmoid groove contained thick creamy pus. The bone was necrotic between the canal and sigmoid groove, down to the bulb. The posterior canal wall was removed and the typical Schwartze-Stacke operation done. A skin graft was placed over the entire middle ear cavity and antrum. All went well until the eighth day, when the patient complained of headache and photophobia, and became restless. The temperature rose to 104°, preceded by vomiting. The condition gradually improved for a week, with no marked variations in temperature. Several consultations were held, and irregular typhoid fever, central pneumonia, and meningitis were suggested. On the eighth day the child became drowsy and irritable, complained of posterior headache, and refused nourishment. After some delay in obtaining permission, an explanatory operation was performed, the writer suspecting an intracranial condition resulting from the previous long suppuration. The child's physical condition at this time was poor. The bone over the sinus being removed, an incision was made an inch long, gelatinous clot removed from the torcular end, establishing a blood current from this direction. The bulb was then curetted, and some firmer clot removed, without, however, establishing a flow of blood. The jugular vein was therefore resected, together with several enlarged glands. The patient's condition was good at the end of the operation, but he never regained consciousness, and died twenty hours afterward. There was no autopsy. The author had since had two other cases, with a similar history, in which early operation resulted favorably. He was unable to say whether or not any other intracranial condition existed in the case detailed, but if so, it was obscure. There were no chills or chilly sensations to suggest sinus involvement. In conclusion, the writer sounded a note of warning, in atypical cases, against delaying too long a search for the cause in the original focus of infection, when the patient did not progress well.

What the Laryngologist May Do for the Correction of Some of the More Common Forms of Defects of Speech.—Dr. G. Hudson Makuen of Philadelphia, after dwelling upon the growth and expansion of the work of the laryngologist, rhinologist, and otologist, continued by saying that they had neglected a field which seemed to him to be of great importance. He referred to that of defects of speech, the treatment of which had either been entirely neglected, or relegated to quacks. The medical man should do all in his power to suppress quackery, both in the interest of suffering humanity, as well as in his own interest. It had been estimated that there were over 300,000 stammerers in the United States alone, and this was only a small portion of those having some form of defective speech. Every one of these cases, in Dr. Makuen's opinion, was a proper subject for medical supervision, and he thought that these disorders of speech should come within the domain of the laryngologist, rhinologist, and otologist, and that defects of vision were scarcely of more importance, than defects of speech. He estimated that the exciting cause in 98 per cent. of all cases of stammering, might be looked for in a morbid condition of some portion of the respiratory tract. Adenoids, enlarged turbinals, and chronic rhinitis, were causes of stammering. The laity and some physicians thought children would "grow out" of speech defects, and, therefore, they became nerve habits before any treatment was given. Dr. Makuen explained why children stammer, and he also explained his treatment, which consisted in the removal of all physical obstructions to normal respiration, and in the teaching of physiological breathing, and the elementary sounds used in language. Digestive disturbances should be corrected. Tobacco and stimulants of all kinds interdicted, and the nervous system supported by nourishing food and plenty of sleep. A little mental science must be judiciously mixed in with the treatment, and suggestion always played an important part. Dr. Makuen had found the use of hypnotism of immense value, as an adjuvant in certain selected cases, and he emphasized the importance of syllabic speech. There were forty-four elementary sounds used in language, represented by the letters of the alphabet. The articulation of a word was a combination of two or more elementary sounds arranged in their proper sequence, and a syllable was a combination of elementary sounds which might be given with a single respiratory impulse. Words of two or more syllables should have as many impulses as there were syllables. Stammerers should be taught to speak, and as far as possible, even to think, in syllables.

Multiple Chronic Sinusitis Operated Upon by the Maxillary Route.—Dr. T. Passmore Berens of New York reported a series of fourteen operations through the maxillary route, with empyema of the maxillary antrum, ethmoid cells, and sphenoid sinus.

The operation, which he described in detail, was performed as he saw it carried out by Jansen of Berlin. Following the description of the fourteen cases, Dr. Berens concluded that all of the patients but one had disease of the sphenoid sinus; in twelve of these, occipital and vertical pains were present; in eight—all with sphenoidal disease—the pains extended also into the face, and were neuralgic in character; while in four cases, the pains closely simulated tic douloureux. These patients were all cured except two, one of which was malignant, and another, in which suppuration returned several times in the sphenoid, each return being marked by an attack of tic. It seemed to the writer that the presence of pain in the vertex and occiput or in trigeminal neuralgia, when accompanied by pus in the posterior nares, was symptomatic, almost diagnostic of sphenoid disease. In twelve of the patients there was pain in the region of the eye, especially in the region of the inner canthus. This pain was explained at the time of operation by the finding of disease in the most anterior ethmoid cells. In all of the cases but one, there was a total absence of frontal sinus disease; and since they were all chronic cases, most of them of many years' duration, it was interesting to ask what factor was present to preserve the frontal sinus from the primary infection, to cure it if it was infected, or to protect it from subsequent invasion by the disease already established in the ethmoid region. In eight of these cases the teeth were found diseased at the time of operation, or there was a clear history at least of dentalgia. The writer believes that many a tooth had been sacrificed, when proper treatment of the antrum would have saved it. A tooth having roots protruding into a suppurating cavity—the roots protected by only a thin periosteal covering—could readily become diseased by contiguity of tissue; and the writer believed that in at least some of his cases this actually had taken place, at least to the extent of producing dentalgia. In all of the cases, except two, there was a complete and permanent relief from pain, following the operation. Of the nine cases operated upon more than a year ago, four had had a return of pus. In two of these the trouble was in the ethmoid region and was cured by subsequent curettage; one was malignant, and one was in the sphenoid. The continued suppuration in the latter case was probably due to a prolongation of the sinus into the wing of the sphenoid bone, or some other similar condition. In conclusion, the operation as described, was advised only after a careful study of each case, and where the hope of a cure by milder measures could not be held out to the patient.

Treatment of Tuberculous Laryngitis.—Dr. S. E Solly of Colorado Springs, Colo., read a paper on this subject. In his opinion, most physicians were too timid in handling the tuberculous larynx, resorting in their blindness to superficial treatment, and to sedatives, in their mistaken kindness, when in most cases they had far better use radical measures.

Dr. Joseph A. White of Richmond, Va., reported a case of mastoiditis, which was complicated by nephritis and erysipelas.

Tinnitus Aurium and Its Treatment.—Dr. W. S. Bryant of New York read a paper on this subject, in which local treatment only was considered. This was found to be the same as the treatment for deafness with few exceptions. Many of these arose because the disturbance was of more delicate nature than that causing a loss of hearing alone. It therefore required still greater care in manipulation. Too energetic treatment might tend to increase, rather than decrease the symptom. In a large proportion of cases the sound-conducting mechanism was at fault, and required treatment more than any other defect in the complicated condition which gave rise to the tinnitus. Neurectomy had been tried in cases of grave tinnitus with unsatisfactory results, owing to the poor technique employed, and the selection of improper cases. Further attempts would undoubtedly develop a comparatively safe and sure method. Treatment in objective tinnitus was chiefly directed to lessening the sounds, and later to dulling the patient's perception of them. In subjective tinnitus, the local treatment was chiefly directed to lessening the perception of the tinnitus by the ear, and the improvement of sound-conduction; secondarily, to lessening the sounds themselves. Most of the tinnitus under this head was dependent on pathological conditions of the mucous membrane of the Eustachian tube and tympanum, which were themselves dependent on like conditions in the nasopharynx. The treatment was worked out on the lines required by a classification of the varieties of tinnitus, which the author submitted.

Symposium on Malignant Growths of the Upper Air Passages.—Dr. F. C. Cobb of Boston discussed the nose and accessory sinuses; Dr. Max A. Goldstein of St. Louis, Mo., the mouth and pharynx, while Dr. D. Braden Kyle of Philadelphia briefly discussed the pathology of malignant growths of the upper air passages.

Adenocarcinoma Occupying All of the Sinuses, Nose, and Orbits.—Dr. W. H. Dudley of Easton, Pa., read a paper on this subject, and presented a pathological specimen. The patient was sixty-three years old, with a history of the previous removal of polypi from nose and nasopharynx, and presented himself with disease of left maxillary antrum and exophthalmos. Antrum and orbit were cleaned out, but growth soon returned, and continued to involve one sinus after another, until the whole anterior portion of the head had become one mass of adenocarcinomatous tissue. Microscopical sections of polypi removed early, were simple adenoma, but all sections examined after the operation, to relieve the exophthalmos, were adenocarcinoma. The case was under observation over two years, and during this time the *x*-ray was used for several months, which resulted in relieving the pain (which was never very severe), and reduced somewhat the size of the tumor, which, however, grew rapidly again as soon as this treatment was discontinued. An examination of the bisected specimen showed practically none of the osseous framework of this part of the head, except the sphenoid and frontal bones, and a portion of these was also absorbed. Several photographs were presented showing the appearance of the case at different stages of the disease.

Malignant Disease of the Upper Air Passages.—Dr. Chevalier Jackson of Pittsburg read this paper. The factors in the etiology of carcinoma were age, sex, heredity, syphilis, irritation, and precancerous benign neoplasms. The sites in the order of frequency were the glottic boundaries, the epiglottis, posterior surface of the cricoid cartilage, interarytenoid fold, aryepiglottic ligament, ventricular bands, the ventricle, and the infraglottic region. The symptoms were dysphonia, hoarseness, aphonia, cough, expectoration of frothy secretion, dyspnœa, hemorrhage, orthopnœa, pain, laryngeal and referred to the ears, dysphagia, odynphagia, fetor, and cachexia. The laryngoscopic appearances might show paralysis of a cord, a more or less diffuse redness, or a protrusion appearing snow-white, dirty gray, pinkish, or reddish, in form papillomatous, warty, with sharply pointed elevations, with intervening rounded granulations, or an ulcer. It might be single or multiple, and was often covered with pus or frothy saliva. The diagnosis would rest upon the age, fetor, cachexia, adenopathy, pain, duration, paralysis of a cord, palpitation of the thyroid cartilage, and the microscopic report. Syphilis, perichondritis, lupus, tuberculosis, chronic laryngitis, blood clots, and hemorrhagic spots, pachydermia, eversion of the ventricle, and benign growths, were excluded. The prognosis as to termination was unfavorable, but not hopeless. In early operated intrinsic malignant disease it was good. In disease extrinsic by origin or extension, and when the lymphatics were infected, it was unfavorable. Prognosis as to duration, from two to ten years, might be promised, if not seen too late. As to recurrence, the prognosis was the same as mentioned of termination. The prognosis as to voice in early thyrotomized intrinsic cases, was fairly good; in late cases requiring laryngectomy, some kind of sound answering for speech might be promised. Treatment might be palliative or radical. Palliative measures included tracheotomy, œsophagostomy (or gastroenterostomy), cleansing sprays and gargles. Serum-therapy, Finsen-light rays, Röntgen rays, and radioactive substances were not yet proven of benefit. Partial endolaryngeal removal of the malignant mass was absolutely unjustifiable, even for the dyspnœa, unless consent to a tracheotomy could not be obtained.

Unless total removal of infection was a reasonable possibility, no operation was justifiable except tracheotomy, œsophagotomy, or whatever else might be planned to prevent or postpone inanition or asphyxia. Radical endolaryngeal extirpation was impossible. Radical measures included transhyoid and infrahyoid pharyngotomy, thyrotomy, partial laryngectomy, and total laryngectomy. Pharyngotomy, transhyoid and subhyoid, were adapted only to disease limited to the epiglottis. Thyrotomy was the operation of election under the following conditions: (1) An intrinsic growth. (2) A limited extent of disease. (3) Malignancy. (4) Suspected malignancy (exploratory thyrotomy). (5) No involvement of the thyroid cartilages. (6) No glandular involvement. Partial laryngectomy was advisable when at thyrotomy removable malignant extension was found. Total laryngectomy with, if necessary, removal of all infected glands and tissues was indicated when the patient desired a chance of cure, with, in any event, increased comfort for a variable period, when the disease was extrinsic by origin or extension, or, though intrinsic, so extensive that sufficient surrounding healthy tissue could not be otherwise removed. Total laryngectomy, with modern technique, prosthetic appliance, and the possibilities of buccal voice, was not the formidable prospect for the patient that it formally was. Preliminary stitching of the trachea to a button-hole in the skin, the avoidance of opiates, the combined Trendelenburg-Rose position, "talking anæsthesia" with chloroform, allowing the patient to "come out" before the stitches were put in, careful post-operative watching, very frequent cleansing of the cannula, and keeping the patient prone after operation—all these would reduce the danger of post-operative pneumonia to almost nothing. Rectal alimentation was a delusion and a snare. Feeding should be by œsophageal tube for a few days.

The use of a brilliant head-lamp facilitated thorough extirpation. The curette had no place in the extirpation of laryngeal malignant disease. It rubbed in the infec-

tion, as a rake buried seed in the soil. A clean cut with knife and scissors through healthy tissues beyond the invaded area was the best method.

Orbital Infection from the Ethmoid Cells, with Spontaneous Opening at the Inner Angle of the Orbit.—Dr. Carl E. Munger of New York said, in studying the literature of orbital abscesses involving the ethmoid region, it was apparent to him that the number of cases recently reported was much less since the rhinologist had been developed, and our knowledge of intranasal diseases had increased and intranasal surgery had become more nearly perfected. This was undoubtedly due to the earlier diagnosis made possible by more extended information as to ethmoid diseases and the greater promptness with which the ethmoid region was attacked surgically. Cases of orbital infection from the ethmoid cells occurred, as was evidenced by the report of such cases. Most of the examples of this occurrence were chronic in character, coming on only after a long duration of ethmoid trouble, but with notable exceptions, *i. e.*, as in a case reported by W. N. Hubbard, in which the orbital abscess came on shortly after a case of tonsillitis, probably of influenzic origin, in a patient with no previous history of ethmoid involvement; and a case reported by Milligan, in which an ethmoiditis followed a severe attack of cold in the head, and this in a short time followed by the appearance of an orbital swelling in the region of the inner canthus. The case reported was not unlike those previously reported.

Diseases of the Salivary Ducts and Glands, and Their Treatment.—Dr. Robert C. Myles of New York pointed out the diseases commonly associated with these organs, and reported five instructive cases. The points of interest that were taught by the histories of these cases were (1) that it was necessary to make a thorough test of every known method, in order to obtain a correct diagnosis in suspicious cases; (2) that the removal of these calculi could best be accomplished by surgical procedures, preferably through the floor of the mouth; and (3) that it was always well, when possible, to probe and dilate the duct, and thus establish and maintain the normal flow of the salivary secretion.

Uses of Rubber in the Treatment of Nasal and Antral Diseases.—Dr. Price Brown of Toronto, Ont., said there were many cases of nasal disease in which, although the passages might be sufficiently open to permit of nasal respiration, yet, owing to accumulation of secretion while sleeping, the mouth dropped open, and oral respiration was the result. In consequence of this, the dry air entering the pharynx absorbed the moisture exuded by the superficial glands, for the lubrication of the mucous membrane, and chronic pharyngitis and laryngitis were the result. For the last twelve years the author had endeavored to remove this cause of oral respiration, by the use of rubber mouth-pieces made of pure sheet rubber, about one-eighth or one-twelfth of an inch thick. A piece was cut to fit the cavity of the mouth between the teeth and lips. The latter are closed over it, hiding it from view, and when worn, oral respiration became impossible, the patient being forced to breathe through the nostrils. One great advantage of all these rubber appliances was that they could be easily made by the surgeon.

Dr. Edward B. Dench of New York reported a case of acute suppurative otitis media, which was complicated by a double pneumonia and septic thrombosis of the jugular bulb. The author resorted to excision of the internal jugular, which was followed by general systemic infection and death.

Papilloma of the Larynx, with Report of a Case of Forty Years' Standing.—Dr. Wm. L. Culbert of New York read a paper on this subject. After a brief résumé of the known facts as to etiology, symptoms, diagnosis, and treatment of this affection, the author reported the following case, which was of interest mainly on account of its long duration, and owing to the circumstance that in spite of an immense amount of instrumental interference, the growth had not assumed a malignant character. The patient first became affected with what was diagnosed as a chronic laryngitis in 1862. Two years later, after much ineffective treatment, she came under the care of Dr. Louis Elsberg, who first recognized the tumor—a large one, filling up the larynx and extending well below the vocal cords. He removed endolaryngeally an amount of tissue equal in bulk to a small hen's egg, and on the growth recurring, removed it again by thyrotomy. The aphonia and dyspnœa of which the patient had complained were completely relieved, and remained absent for over twenty years, when a return of the growth was apparent, and she came under the care of Dr. Rufus Lincoln. He removed the ever-recurring tumor many times during the next ten years. Two or three years of comparative freedom from symptoms followed, when the patient came to Dr. Culbert in a desperate condition, from dyspnœa, and complete aphonia. Examination revealed a papillomatous growth covering in the entire larynx, except a small opening, which would admit a thin lead pencil, through which space respiration had to be carried on. The tumor was attached by a broad base throughout the right and upper parts of the larynx, to the epiglottis, and to a lesser extent to the right side of the larynx. A portion was immediately removed to relieve the impending suffocation, and at subsequent sittings the remainder of the growth taken out with cutting ring forceps. Restoration of the voice and free respiration were accomplished, but the growth increased in size when let alone. Examinations were made by different pathologists for all three surgeons. The tumor removed by Elsberg was of a mixed character, evidently springing from the fibrous tissue, but suggesting in its superficial portions, a possible malignant tendency. The growths taken out by Lincoln and the writer were papillomata, pure and simple. Drawings of the tumor, as observed by the different surgeons who had had charge of the case, were submitted, making a very complete record of the case.

Dr. Arthur B. Duel of New York reported cases illustrating difficulties in the diagnosis of mastoid complications.

Dr. James F. McCaw of Waterbury, Conn., cited four interesting cases of mastoiditis. The first was one of acute suppurative otitis media; mastoiditis; subperiosteal mastoid abscess; perisinus epidural abscess, which was operated on, with recovery. The second was one of acute suppurative otitis media; double mastoiditis; operation and recovery. The third was one of acute suppurative otitis media; mastoiditis; operation and recovery. The fourth was acute suppurative otitis media; mastoiditis; epidural abscess; mastoiditis; operation and death.

The Relation of Diseases of the Stomach to Affections of the Mouth, Nose, and Throat.—Dr. Robert Levy of Denver, Colo., said that a careful review of laryngological literature impressed one with the fact that while there existed a relation between diseases of the upper air passages and those of the stomach, this relationship was not well-defined, nor was the interdependence of diseases of the stomach and those of the mouth, throat, and nose separated distinctly from affections of the gastrointestinal tract, and, in fact, from those of the entire digestive system. Many diseases of the mouth, nose, and pharynx and accessory cavities resisted treatment directed purely to the relief of the local conditions until measures intended to correct general disorders were instituted. Three positive statements might be made clinically: (1) That certain affections of the upper air passages and their adjacent cavities were causative in a measure of some form of stomach disturbance; (2) that certain stomach disturbances were the cause of certain affections of the upper air tract; (3) that the relationship existing between digestive disturbances and certain diseases of the upper air passages was so close that treatment must necessarily involve attention to both conditions. Although no direct causative relation could be traced between diseases of the alimentary canal and certain affections of the mouth, they

might be and frequently were associated. Among the diseases of the nose which were more especially associated with gastrointestinal affections were vasomotor rhinitis, nasal irritation, and red nose. Urticaria of the mucous membrane of the throat was a serious and might possibly be a fatal affection, and was largely dependent upon digestive disturbances, as was well-known to be the case in urticaria of the skin. Among diseases of the larynx, certain nervous affections, such as hyperæsthesia and laryngeal spasm, were found attended with disturbed digestion. Although diseases of the stomach could not be said to be indisputably caused by affections of the mouth, nose, and throat, or indisputably the result of diseases of these organs, the correlation was so close that successful management of both depended largely upon recognition of this interdependence. This still further emphasized the thought to which men working in special lines had called attention, that the entire human organism was one intricate mechanism in which local disorders were frequently but manifestations of constitutional affections.

Bezold's Variety of Mastoid Disease Complicating Diabetes Mellitus.—Dr. S. MacCuen Smith of Philadelphia contributed a paper on this subject, in which he suggested the following points as worthy of consideration: (1) Aural complications of diabetes mellitus might originate primarily in the mastoid cells. (2) The process might be manifested by the classical mastoid symptoms, without involving the tympanic cavity. (3) This condition was peculiar to diabetes mellitus. (4) The term diabetic ear should be limited to those cases in which the disease began as a primary osteitis of the mastoid, or in which primary tympanic involvement and rapid mastoid complications seemed simultaneous. (5) While the writer believed it advisable to reduce the amount of sugar, when possible, in those cases showing an excessive glycosuria, unless the urgency of the local symptoms demanded immediate operation, he had to report, however, that he had not met with any cases that terminated in what could be called post-operative coma.

The Value of Early Incision of the Membrana Tympani in the Treatment of Acute Suppuration in the Middle Ear.—Dr. Francis R. Packard of Philadelphia contributed a paper on this subject. In February and March of the present year there were many grippe cases characterized by the development of acute suppuration in the middle ear. The cases all presented certain definite peculiarities, namely, the abscesses developed with great rapidity, and the pain continued intense for some time after the rupture of the drum had occurred, and in spite of free drainage of pus from the middle ear. The author instanced cases which occurred in private work, where he was able to follow them up. In every case in which early incision in the drum membrane was practised, there was almost instantaneous relief from pain, and the discharge ceased within a few days. In cases in which the drum ruptured spontaneously, the patient's pain and discharge continued for a much longer time. The author advocated the use of gauze drainage, believing that to be the most efficient means of avoiding stagnation of the discharge, pain, and mastoid involvement.

Officers.—The following officers were elected: *President*, Dr. F. C. Cobb, Boston, Mass.; *Vice-Presidents*, Southern Section, Dr. Wm. Cheatham, Louisville, Ky.; Middle Section, Dr. Thomas Hubbard, Toledo, Ohio; Eastern Section, Dr. S. MacCuen Smith, Philadelphia; Western Section, Dr. W. B. Shields, St. Louis, Mo.; *Secretary*, Dr. Wendell C. Phillips, New York, N. Y.; *Treasurer*, Dr. Ewing W. Day, Pittsburg, Pa.

Boston, Mass., was selected as the place for holding the next annual meeting.

Population of England and Wales.—Fewer persons died and a less number were born throughout England and Wales last year than in 1902, while in London itself both births and deaths were the lowest ever yet recorded.

New Instruments.

UNIPOLAR X-RAY.

By SAMUEL STERN, M.D.,
NEW YORK.
RADIOTHERAPIST TO DR. LUSTGARTEN'S CLINIC AT THE MT. SINAI HOSPITAL; CLINICAL ASSISTANT TO THE SKIN DEPARTMENT OF THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

Amongst the defects of the Crookes vacuum tubes of to-day—as they are used for the production of *x*-rays for therapeutic purposes—perhaps the most glaring is that they must necessarily be connected with both poles of the apparatus. This makes practically a stationary apparatus, does not permit handling with any degree of ease, and often prevents us from using the effective rays on surfaces not easily reached, or those situated in the various cavities of the body.

A number of attempts have been made to construct tubes with long cylindrical projections, which may be used in cavities. These projections are from six to eight inches long, which brings the distance from the anode, where the rays are generated, to the tip of the projection, where they are emitted, up to ten inches or more. As the projection can rarely be passed up directly to the lesion treated, we must allow for several additional inches of distance, reckoned from the source of the ray. Considering that the intensity of exposure is in inverse square ratio to the distance from the source of the ray, we find that, allowing for a distance of about twelve inches, these exposures would have to be greatly prolonged to be effective.

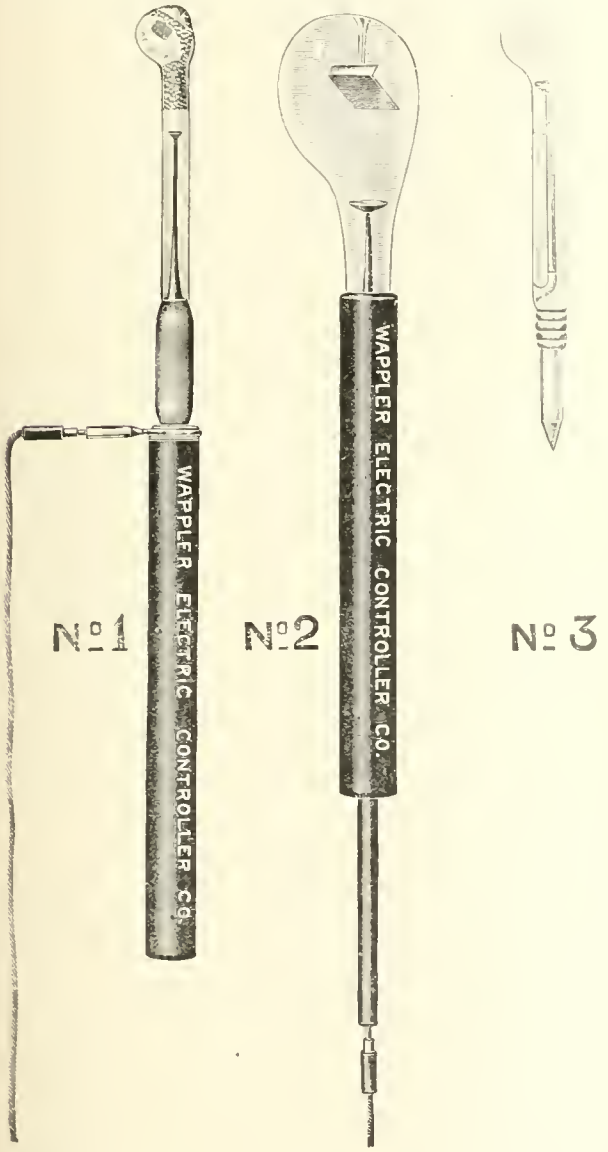
This is a very serious drawback in treating lesions situated in cavities (such as the throat, for instance), where the time of exposure, on account of the inconvenience of keeping the tube in position, is of vital importance. The rays as they are emitted from the cylinder travel in all directions, and it is a very difficult matter to protect the healthy surrounding tissue from their injurious effects.

An attempt has been made to obviate this by manufacturing tubes of lead glass, which obstruct the rays, the tip of the projection alone being made of glass, which is pervious to the rays. These tubes are made with a handle, which permits easier manipulation, but as they are necessarily connected with both poles and are of rather bulky dimensions, their manipulation is so difficult, that it is practically impossible to administer rays from them, and to regulate the current from the machine properly without the aid of an assistant.

The anode of these tubes becomes extremely hot in a very short time (in one minute or even less), and the current must be shut off several times to allow it to cool, before an effective exposure can be given. In treating diseases of some of the cavities, these tubes are entirely valueless. Affections of the larynx or œsophagus (cancer, etc.) cannot be reached by them, for when they are passed into the mouth, the angle at which they may be depressed is not enough to direct the rays sufficiently downward to strike the affected parts. The rays will pass through the pharnyx and back of the neck. This, to the best of my knowledge, is a defect found in every device used in treating these cavities at the present day.

In experimenting with various forms of high-frequency resonators, I have found that if two Leyden jars are connected by their internal armatures to the two poles of a coil, and the external armatures are connected to a spiral coil having a few strands of thick wire, followed by spirals of fine wire, the current which is derived from the inner extremity of the spiral, when connected with one pole of a Crookes vacuum tube will produce *x*-rays. This arrangement is very similar to the apparatus known as the Oudin's resonator.

This method enables us to use vacuum tubes of different sizes and shapes, small enough to be passed into the throat, or any other cavity, with the position of the cathode and anode arranged in a way that the rays can be made to travel in any direction desired. For instance, in the treatment of the larynx the tube can be passed into the throat over the larynx, the rays being directed downward, so that they will strike the larynx directly without being compelled to travel through any intervening tissue. In treating the œsophagus, these bulbs can be made so as to be attached to a flexible rubber tubing, which may be passed down to the lesion to be treated. While limited time and opportunity have not permitted me to make experiments in regard to passing these bulbs into the stomach itself, I see no reason why an arrangement similar to that devised by Exner* and Einhorn,† for the introduction of radium into the stomach, should not be used as effectively in introducing these bulbs. The fact that they are attached by only one pole, and that the bulbs can be made of any desirable size, should make it a simple matter. Similar methods can also be used for the introduction of these bulbs into the rectum or vagina. The tubes which I have used are simply small vacuum bulbs with a cathode fused into one extremity, and an anode into the other, placed at the usual angle. The cathode extremity of the tube is attached to an insulated glass handle similar to those used in treating by high-frequency currents. This is screwed into a wooden handle, with a wire running through it, inserted to the extremity of the cathode. The whole arrangement appearing as an ordinary elongated high-frequency tube, with the exception of the infused cathode and anode at its extremity. The anode has no attachment on the outside of the tube, and is merely used to direct the rays toward the point desired. Experiments tend to show that the anode is superfluous, and that the rays can be generated directly on the glass. These bulbs, on account of their minute size, become hot in a short time, but considering that the source of the rays can be brought so closely to the lesions to be treated it is seen that a half-minute exposure at a distance of perhaps one inch from the source of the ray is equal to a number of minutes with the tube at the usual distance. There is some sparking from the surface of the tube, due to the high-frequency currents passing through it, which can be remedied by enclosing the entire tube in rubber, with the exception of the parts through which the rays are desired.



I think that the most important use of this method will, perhaps, be in the treatment of skin diseases. We find that a great variety of skin diseases are very beneficially effected by the *x*-rays. We also find that the application of the high-frequency currents has established itself as a very valuable adjunct in the treatment of diseases of the skin. By this method both treatments can be administered simultaneously, as a powerful high-frequency current is continually passing through these tubes to the surface treated. Another very important advantage is that the tubes can be made in all sizes, enabling us to use one just large enough to cover the surface treated, doing away with all sorts of shields, and by applying the tube in direct proximity with the surface, there is no question as to the proper direction of the rays in relation to the lesion to be treated. There is the very important item of a saving of time, since the source of the rays is brought so close that the required length of exposures is very much diminished.

The new method of obtaining *x*-rays should prove of great value in dentistry. It has been found that various affections of the teeth (pyorrhœa alveolaris, for instance) are greatly benefited by *x*-rays. Here the bulb can be passed into the mouth directly over the affected teeth; and the same can be done when it is desired to take radiographs of the roots of the teeth and maxillary bones.

When the high-frequency currents generated in the solenoid (spiral wire) enter the tube at the extremity of the cathode, part of it is changed into cathode rays, which are discharged as such from the surface of the cathode, impinging on the anode (or on the wall of the tube if no anode is present), at which point they are changed into *x*-rays. A considerable portion of the current travels unchanged on the surface of the tube, from where it is given off in the form of high-frequency sparks. The strength of these sparks can be increased or diminished at will, depending upon the distance the tube is held from the surface treated. When the tube is held in contact with the parts treated, we get the maximum amount of *x*-rays with the minimum amount of sparks, the high-frequency currents passing to the surface as such without producing any sensation due to the dynamic effect of the sparks. In the smaller tubes, in which the cathode is very near the wall of the tube, it is advisable to have the glass stem through which it

**Wiener klinische Wochenschrift*, January 28, 1904.
†MEDICAL RECORD, March 5, 1904.

passes, insulated, to avoid the sparking from the cathode to the surface of the tube.

In the accompanying illustration is shown a small Crookes' tube with an insulated stem. This tube has a cathode which is cut short in the stem 1¾ inches from the anode. The anode consists of a small disk of platinum, placed at an angle of about 45° to the cathode, fused into the upper and outer part of the tube, so as to direct the rays downward. On the outside of the tube is a small metallic cap, placed over the outer extremity of the anode, to prevent sparking of the wire. The neck of this particular tube and the upper and outer part are covered with a coating of bronze, which acts as a sort of condenser. This is not absolutely necessary and has the disadvantage of increasing the intensity of the high-frequency spark.

This defect may be partly remedied by covering those parts of the tube from which the ray is not desired, with rubber or other non-conducting substance. This tube is adapted for the treatment of lesions of the mouth, larynx, or other cavities.

The lower extremity of the tube is grooved, and can be readily screwed into its handle. The handle of figure 1 is of a similar character to that used for ordinary high-frequency electrodes. It has the advantage that the current enters at its upper extremity, while in the handle of figure 2 the current enters in its lower extremity, requiring it to pass through the handle, causing a considerable waste by auto-conduction. The tube seen in figure 2 is an ordinary small Crookes vacuum tube, adapted for the treatment of surface lesions, where the combination of *x*-ray and high-frequency currents may be indicated; or for lesions situated in regions not easily reached by the larger tube. These tubes must all be of a medium or rather low vacuum, as the higher the vacuum the more current is required to make the tube fluoresce, and the more surface high-frequency discharges will be given off.

Figure 3 shows a tube without an anode, designed for the treatment of cavities. The glass wall of the tube acts as target for the cathode ray, and where the latter impinges it is changed into an *x*-ray. This is seen through the fluoroscope as a small circle directly opposite the cathode.

With this tube the source of the ray can be brought into direct contact with the lesion treated. The only disadvantage these tubes possess is that it is somewhat more difficult to direct the rays in the various directions required.

While limited time did not permit me to experiment with tubes in which the cathode was fused in at different angles, so as to enable us to direct the rays to any part of the tube desired, I see no reason why this should not be feasible.

In closing, I want to express my thanks to Dr. Charles W. Allen for his valuable suggestions, and to Messrs. R. and F. Wappler for their assistance in my experiments.

141 East Seventy-fourth Street.

A New Cure for Drunkenness.—The Norwegian authorities, who do not make light of the subject of alcoholism, have conceived an original method of curing drunkards of their vice. The "patient" is placed in a room, which he is forbidden to leave, and all outside communication is cut off. When he is once under lock and key, his nourishment consists in great part of bread soaked in port wine. The first day, the drunkard eats his food with pleasure, and even on the second day he enjoys it. On the third day he finds that it is always about the same thing, and on the fourth day he becomes impatient, and at the end of eight days he receives the wine with horror. It seems that the disgust persists and that this homœopathic cure gives unexpected results.—*Le Bulletin Médical.*

Therapeutic Hints.

Torticollis.—A weak galvanic current is frequently very serviceable. The positive pole should be placed just below the occiput and the negative pole allowed to act upon the contracted muscles for from five to ten minutes.—H. B. Sheffield.

Erysipelas.—

M. et Sig.: One-half teaspoonful in water morning and evening. —Bartholow.

Myxœdema.—Cold has a very disastrous effect on myxœdema, patients always feel worse during winter and on the colder days. The indication thus is to supply climatic and artificial warmth. In commencing thyroid treatment small doses are advised.—H. C. Drury.

Amyl Nitrite in Hæmoptysis.—Francis Hare finds that inhalations of amyl nitrite arrest hæmoptysis instantaneously. He has tested it in four cases of phthisis and one of mitral obstruction with very satisfactory results.—*Australasian Medical Gazette.*

Antidysenteric Serum.—Rosenthal derived an antidysenteric serum from the inoculation of animals, first with dead cultures of the bacillus, then with living cultures, and finally with the toxins. By the use of this serum it is claimed that the percentage of mortality is reduced by one-half.—*Deutsche medizinische Wochenschrift.*

Surgical Suggestions.

Lacerations of the Cervix.—Suture cervical injuries at the close of labor when they seem to be the cause of postpartum hemorrhage. Sew up all the cervical tears in the first week in conjunction with the perineal operation when the pelvic floor injury is of such a character that a few days' delay is desirable. Restore severe injuries to the cervix from the third to the tenth day after delivery.—R. L. Dickinson

External Thrombotic Piles are readily cured by incising them, turning out the blood clot, and then suturing the cut ends under antiseptic precautions. Old, hypertrophied tags may be excised, and the wound closed by sutures. Both of the latter operations may be done under local anæsthesia if divulsion of the sphincter ani is not necessary for this or complications.—Geo. K. Sims.

Pyorrhœa Alveolaris.—Teeth once loosened can rarely be tightened, and their retention is a positive menace to the health of the mouth. Successful treatment lies in the fidelity with which the toxic irritative matter is removed from the surfaces of the teeth and rational after-treatment maintained.—D. D. Smith.

Cocainization in Abdominal Surgery.—M. Chaput recommends local cocainization in abdominal surgery. For very nervous subjects he considers it more suitable than a general anæsthetic. When the agitation of the patient makes the continuation of the operation under cocaine impracticable, it is necessary to resort to a general anæsthetic, the effects of which are simply increased by the previous cocainization.—*Gazette Médicale de Paris.*

The Yeast Poultice.—E. J. Kempf describes his method of making a yeast poultice as follows: Take of beer yeast, one quart; corn meal, finely sifted, one pint. Mix the yeast with the corn meal. Place the mixture near a fire till it rises. Mix with the thin raised dough about two ounces of finely powdered charcoal. Apply the mixture on a thick cloth directly to the affected part and renew every twenty-four hours. It becomes dry and adheres to the parts, but it can be removed readily with warm water. This mixture is one of the most efficient antiseptic poultices for various septic conditions, such as gangrene, foul ulcers, erysipelas, eczema, extensive injury of tissues, etc. The writer then gives the history of various cases in which he has used this remedy with the happiest results. In one case the patient had shot himself with buckshot, and the whole arm, which was badly injured, became much swollen, œdematous, and covered with blebs. An amputation seemed unavoidable. The yeast poultice was used on the arm for nearly three weeks, and the patient recovered. The writer believes that this treatment was the only thing that saved the arm. He suggests that probably the yeast germs in the yeast poultice overcome the bacilli in a similar manner to that which the white corpuscles in the blood employ when fighting germs in the system.—*Indiana Medical Journal.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 24, 1904:

	Cases.	Deaths.
Measles	43	4
Diphtheria and croup	224	16
Scarlet fever	58	4
Smallpox	2	...
Varicella	3	...
Tuberculosis	305	145
Typhoid fever	93	21
Cerebrospinal meningitis	...	19

Rush's Treatment of Hæmoptysis.—The following copy of a prescription by Rush was kindly sent us by Mr. G. Grosvenor Dawe, Secretary of the Society of American Authors. The original is in Mr. Dawe's collection of documents written or signed by various heroes of the Revolutionary War.

Advice for Mr. Rodgers: Please to take half of one of these powders every morning, noon, and night in a little sugar and water. They are composed of half an ounce of nitre, and two grains of tartar emet, intimately mixed and divided into twelve doses. As soon as you have taken as many of these powders as shall reduce your pulse to its normal activity, or remove the present feeble degree of tension from it, leave them off and begin and take a small teaspoonful of pale bark every morning and evening. If it should purge you, take two or three drops of laudanum in each dose. If it should produce costiveness, take four or five grains of rhubarb in each dose.

While you are taking the bark, your diet and drinks may be of a cordial, but not very nourishing character—such as salted meat and salted fish in small quantities, fresh fish, oysters, eggs with the common table vegetables (cabbage excepted). With these may be taken weak claret or porter and water or small beer. The quantity of liquids taken in a day should not much exceed a pint. Milk should be avoided in your diet, and tea and coffee taken sparingly and never strong. Four or five small meals should be preferred to one or two large ones in a day.

During the use of the above remedies, gentle exercise should be used daily, but never before breakfast, nor in damp weather, nor after night, nor until fatigue be induced.

Suit your dress to the change in the weather, always preferring clothing that is a little warmer than is customary in health. Defend your feet with uncommon care from wet and cold.

Go to bed early. Sleep alternately upon both your sides, and never upon your back.

Carefully avoid loud and long reading, singing, and lifting heavy weights.

Should the discharge of blood from your lungs return at any time, instantly swallow a papspoonful of dry salt. Afterward take twenty or thirty drops of laudanum, if the salt does not check the bleeding. Lose ten ounces of blood as soon as convenient afterward. Repeat the bleeding if your pulse be tense, and apply blisters to your wrists, and take the nitre and tart. Emet: as formerly directed, and the same time live upon nothing but rice and fruit and mild table vegetables, with a little water or Balm tea. When these remedies have restored your pulse to its natural state, return to the use of the bark, and the cordial diet and drinks before mentioned.

Should a troublesome cough attend or follow your disease, take from twenty to thirty drops of laudanum every night at bedtime, and drink occasionally of flaxseed tea or barley water. If these remedies do not remove it, recourse should be had to salivation. If a cough do not succeed, and the remedies remove your present indisposition, it will be advisable to travel next summer to the northward in order to prevent a relapse, and to confirm your health. Benj. Rush

December 21, 1807.

The Menopause.—J. L. Ellis finds the matter of the menopause a neglected field of research, and yet probably this epoch in a woman's life is more important than any other. The free action of the emunctories should be carefully maintained throughout this period. The menopause affects the kidneys by checking secretion. It is not yet determined just how this is done. Attention to food products and proper exercise should be given the preference over drugs wherever this is admissible. Milk and buttermilk are good diuretics, and so is water. In regard to the bowels, the writer inclines to the use of cascara and epsom salts. The former should be taken regularly in 3 or 5-grain doses every night, or as often as may be needed. The salts are especially good for overcoming the congestion of the pelvic viscera. Preferable to either, however, is the use of laxative foods and fruits at breakfast. An adequate supply of liquids must not be forgotten. The morbid or peculiar action of the skin is most evident during the menopause, principally in two ways, flushings and sweatings. It is natural enough that the extensive area of cutaneous nerve-endings should share in the common reflex or sympathetic disturbances, so-called, so prevalent at this period. There may be other disturbances, such as eruptions, and œdema. During these periods women are usually in a sensitive, nervous state in a condition of general hyperæsthesia. Excitement is apt to favor flushings and should be avoided. As to treatment of this condition, the general condition of the patient must be considered and everything possible should be done to insure as normal health as can be secured. The bromides are given for excitability. In the case of feeble women the additional benefit of nux vomica or strychnine should be offered. Stimulation of renal activity often cures excessive sweating. Moderate daily exercise, especially in the open air, cold sponge bathing, or sponging the surface with alcohol, or tepid sponge baths, in the very weak, tone up the nervous system, so that sweating due to relaxation soon disappears. The circulation should be good, and the respirations deep and frequent. A moderate amount of exercise insures this better than any drug can do under most circumstances. One of the best exercises for the lungs is singing. Change of life is not a disease. No special disease is peculiar to this period. The key to the treatment, according to the writer, is to remember the higher persensitive state of the reflexes.—*The Mobile Medical and Surgical Journal.*

A Case of Hemihypertrophy in Which the Internal Organs Were Affected.—Robert Hutchinson reports the case of a child born at full time, the mother's health having been good during pregnancy. The child's abnormal condition was noted at birth He was healthy and well-developed. The viscera were healthy. There were three small capilliary nevi in the skin at various points. The asymmetry involved the left arm and leg, and to some extent the trunk also, but the head, face, and tongue were quite symmetrical. There was no abnormality of the digits. The condition in the leg closely resembled a diffuse lipoma. The left forearm was an inch and a half greater in circumference than the right, the left calf two inches greater than the right, the left thigh an inch and a half larger than the right. There was no difference in the length of the limbs on the two sides. The left chest and abdomen were larger than the right. The child was attacked by bronchopneumonia and died. Post-mortem examination showed this increased thickness on the left side to be due entirely to an increased deposit of subcutaneous fat There was no evidence of any mastoid tissue or vascular dilation. The bones on the left side were no thicker than on the right. The brain was normal and symmetrical, but most of the paired organs were decidedly larger on the left side than on the right. The thyroid cores were symmetrical, but the left side of the thymus was larger than the right. The writer believes such a condition as the above must date back to embryonic life and be the consequence of unequal segment action in the ovum.—*The British Journal of Children's Diseases.*

The Factor of Heredity in Atrophic Rhinitis.—Lewis S. Somers believes that there are three conditions which present strong evidence of hereditary transmission in the etiology of genuine atrophic rhinitis, viz., certain deviations from the normal in the osseous frame work of the nasal chambers, a tendency toward localized epithelial metaplasia, and possibly the attenuated taint of syphilis or tuberculosis. The first consists essentially in an abnormal width of the nasal fossæ, with an anterioposterior flattening. This condition is more often seen in persons with broad, low noses. The explanation of the hereditary factors concerned in this affection is to be found in this structural alteration, and it seems probable that the family tendency is essentially based upon such a form of nasal architecture. Epithelial metaplasia is invariably found in atrophic rhinitis and consists in general in the transformation of the ciliated columnar cells into the flat, squamous variety. There is great difficulty in determining the exact period when this metamorphosis took place. As Meisser has stated, for the advent of atrophic rhinitis there must be two factors at work; first, epithelial metamorphosis, and secondly, wide nasal fossæ. An inherited pathological taint seems to be evident in the majority of cases which become prominent at an early age, and usually it is possible to obtain a history of tuberculosis or syphilis in the parents or grandparents of the child. Somers wishes to emphasize the apparent fact that heredity plays an essential rôle in the vast majority of cases of atrophic rhinitis, and this factor is manifested through the aberrant nasal form, the epithelial metamorphosis, and possibly the transmission of an inherited pathological taint.—*Pennsylvania Medical Journal.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service during the week ended September 17, 1904.

A CRITICAL REVIEW OF THE STUDY OF CANCER.*

BY ANNA M. GALBRAITH, M.D.,
NEW YORK.

A REVIEW of the study of cancer will be most profitably divided into three periods: (1) The observational or clinical study of cancer, dating from Hippocrates; (2) The pathological study of cancer, beginning with the discovery of the compound microscope in 1830; and (3) The surgical treatment of this disease, from the establishment of antiseptic surgery by Lister in 1881.

Since my paper is to be followed by others on "The Pathology and Bacteriology of Cancer," as well as on "The Medical," "Surgical," and "*X*-ray Treatment of Cancer," most of my time will be devoted to a review of the clinical study of this disease.

Taking up first those divisions of my subject to which I shall devote the least attention, we will consider them in the following order: The surgical treatment of cancer; the pathological study of cancer; and lastly, its clinical study.

The Surgical Treatment of Cancer.—Ambrose Paré (1634) said, "If the cancer is small and in a part which will suffer amputation, first purge and bleed the patient, and if the strength of the patient will admit, amputate." He described the operations for cancer of the breast and for cancer of the lip.

More than one hundred years later that famous surgeon John Hunter wrote and advised extirpation, provided the whole disease could be safely extirpated; that is, if the disease occurred in an organ or a part which could be amputated, as in the breast or limb. But if the tumor of the breast should be fixed, or if there was great enlargement of the lymphatic glands, he advised against operation.

Johnson, in the prize essay of 1808, awarded him by the Royal College of Surgeons, said, that in all operable cases the operation should be performed as soon as there was any reason to suspect the nature of the disease. Any enlarged lymphatic glands should be carefully removed. "As to cancer of the uterus, here the disease presents itself in a part that does not admit of extirpation, therefore all that can be done is to palliate the symptoms and endeavor to prolong life." He said that the operation for the removal of the eyeball had not been attended with success; but that a few cases of operation for the removal of the tongue had been successful.

The only wonder is that, before the brilliant discovery of anæsthesia by Morton in 1846, there should have been any considerable operations for cancer at all. And when a surgeon, in a description of an operation for cancer of the breast, calmly says, that the patient may either sit up or lie down, but that she must be securely held by attendants, we are convinced that the heroes of ancient times did not all die on the field of battle.

To be of any value, from a statistical point of view, as to the percentage of cures following early operations, nothing previous to the establishment of the antiseptic treatment by Lister in 1881 should be quoted, since it is obvious that before that time more patients probably died of sepsis following the operation than died from a recurrence of cancer.

The Pathological Study of Cancer.—The pathological study of cancer really began with the first post-mortem examinations and the study of the macroscopical appearances of the tumors. Hunter was the first to make a careful study of tumors and cancer, and he is credited with having laid the foundation for the anatomico-pathological study of tumors.

Autopsies began to be made in the first years of the nineteenth century. Carmichael, in 1809, described a case of post-mortem examination which seemed to impress him greatly. "Upon opening the intestines the cause of the adhesion to the uterus as well as of the constipated state of the bowels became apparent; for the carcinomatous substance had extended from the uterus into the very cavity of the intestine, which it nearly filled, allowing a space only sufficient to admit a common quill, for the passage of the intestinal contents. The colon, also, was tied down by two firm gristly bands which proceeded from the left edge of the uterus, and like ribbons encircled the intestine."

A discovery that revolutionized pathology was the invention of the compound microscope. Although this instrument was invented in 1590, it was not until 1830, that it was so far perfected as to be of value in scientific research.

In 1838 Schleiden and Schwann gave to the world their famous cell theory. In the same year Müller's work on the origin of tumors established the cellular nature of cancer and other neoplasms. Müller believed that the constituent cells of tumors were derived from the formative fluid exuded from the blood (blastema), which was nothing else than the coagulable lymph of Hunter under another name.

In 1849 John Hughes Bennett published his work on "Cancerous and Cancroid Growths." In this work fifty-six cases are given, with the history of the patient, the record of the autopsy, macroscopical findings, and microscopical examinations. Bennett described the cancer cell and the appearance of its retrograde course. This last he believed offered strong proofs of the spontaneous cure of cancer in an organ with an excess of fat formation or of mineral deposition. Lebert, he said, has endeavored to establish the existence of the cancer cell as pathognomonic, that it may be distinguished from every other kind of cell formation and at once indicate the nature of a cancerous growth. But he agreed with Müller, in thinking that no single element was diagnostic, and that the pathology of cancer was wholly theoretical.

In 1855 Rokitanski published his celebrated work on Pathological Anatomy. He defined sarcoma as a benign, local affection, affecting the areolar, fibrous, submucous, muscular and intermuscular tissues, the bones, glands, and, in rare instances, the brain; and

*Read before the Alumnæ Association, Woman's Medical College of Pennsylvania.

carcinoma as heterologous growths which frequently originated and existed as local evils, but he believed that they were far more commonly associated with a dyscrasia, which, in fact, he said, often preceded and engendered the cancer. He thought the crasis was mainly due to an excess of albumin and fat in the circulating fluid. Infection, he said, took place through the entrance of the cancer cells or of the cancer blastema into the blood-vessels and lymphatics. He observed that the most frequent termination of cancer was by suppuration with necrosis; that the suppuration became deadly through the infection of the blood and pyæmia. However seldom he wrote, that the extirpation of cancer proved successful, its spontaneous cure was a still greater rarity. He thought that a cure might be brought about by necrosis and partial rejection of the tumor, or else by its more rapid death and expulsion; or by processes of cure bearing the character of involution or a decadency of the cancer by saponification effected by the conversion of protein substance into fats; or a wasting of the tumor with condensation, solidification of its blastema and the liberation of the salts of lime.

Virchow accepted the cell theory of Müller, but denied the blastemal origin of cells, and substituted for this that famous formula, "*omnis cellula e cellula.*" Where a cell arises there a cell must have previously existed. Virchow also adopted the irritation and chronic inflammation theory.

Cohnheim's theory of the etiology of tumors is, that in the very early stages of embryonic development more cells are produced than are needed for the building up of the parts concerned, so that a quantity of cells remain unappropriated, which, *owing to their embryonic character*, are endowed with a marked capacity for proliferation. As proofs of this theory he cites the facts that portions of embryonic tissue—that is, pieces taken from a fœtus yet unborn—introduced into a new foreign organism, not only live, but grow, in a very surprising way; the hereditary transmission of the same kind of tumor in a number of successive generations of the same family, which is particularly well-established for carcinomas; and the congenital appearance of tumors, whether inherited or not. Cohnheim does not claim that the tumor itself is congenital, but that its rudiment is. He assumes simply an excess of cells as compared with the physiological standard, out of which excess a tumor may ultimately develop. He believes that traumatism may play some part in the development of tumors, and that it is, perhaps, the resistance of normal tissues which hinders the development of abnormal germinal material in many individuals.

Virchow has regarded the fact that epithelial tumors evince a special disposition to attack the orifices of the body, as the lips, tongue, rectum, or uteri, and so forth, as strong proof of the theory of mechanical irritation as an etiological factor in the production of tumors. While Cohnheim argues that during the embryonic development most of these localities are the seat of certain complications. There occurs at the various orifices either a prolongation of the epiblast inward, or a conjunction between it and another epithelial tube, or the like, and that some irregularities during this process would easily give rise to a group of epithelial cells—that is, to the rudiments of a tumor. That with the fact established that the embryonic forms the starting point for tumors, the sole positive condition for their development is an adequate supply of blood.

In thus taking the criterion of malignancy as the falling off of the physiological resistance of the parts bordering on, or remote from, a tumor, Cohnheim assumes that the ruthless extension and generalization is to be sought for in the behavior of the organism, rather than in the properties of the tumor itself, which has been the belief hitherto of the pathologists and surgeons. Virchow says that every tumor has a period of innocency, which would be a proof that the malignancy does not depend on the nature of the tumor. So that the theory is rendered highly plausible that the benign or malignant character of the tumor depends solely on the behavior of the remainder of the organism. The physiological resistance in the neighborhood of the growth must, he thinks, be diminished in order that a tumor may become locally malignant, and similarly there must be a falling off in the physiological resistance of the other tissues of the organism for a tumor to become generalized.

The commonest mode of generalization is through the lymph streams; but penetration into the blood vessels is also a very common event. The proliferating epithelium possess a power to penetrate into connective tissue altered by inflammation. Waldeyer has called attention to the frequency with which inflammatory changes may be observed in the connective tissue bordering on cancer; so here, too, traumatic agencies play a part. Greater importance would seem to be attached to advanced age, as bearing on this subject. Thiersch was the first to lay tress on the importance of this factor for the etiology of cancroid. He pointed out that in old age the connective tissue of the body atrophies, and is consequently no longer capable of opposing the ingrowth of the cutaneous epithelium, which retains to the last a greater vitality to produce cells. That carcinomata do not make their appearance until about the fiftieth year of life, when senile decay lessens the physiological resistance of the tissues.

Cohnheim's views, that the degree of malignancy of the tumor is to be sought for in the behavior of the rest of the organism rather than in the tumor itself, is emphasized by Bland-Sutton. He says, that the clinical and pathological study of cancer exhibits not only peculiarities of cancer in regard to its mode of growth, infection of the lymph-glands, dissemination, and the manner in which it destroys life, but that the course of carcinoma is greatly modified by the age and constitution of the patient, and that the same disease in two patients, apparently alike in age and environment, will progress so differently, that no surgeon can predict with any reasonable certainty the expectation of life, the result of the operation, liability to dissemination, or the chances of recovery.

The Clinical Study of Cancer.—We will now turn our attention to the third and last division of our subject, namely, the clinical study of cancer. Aside from the interest involved in the study of medical history, a review of the clinical study of cancer should be most instructive, calling attention, as it does, to etiological factors repeatedly observed by close students of this subject; since on these etiological factors must be based the study of the lines of treatment of this fatal disease.

It must be borne in mind that before the discovery of the circulation of the blood by Harvey in 1616, the whole field of medicine was enveloped in a haze of mystery and superstition. Although in the latter part of the seventeenth century, Sydenham laid the foundation for the clinical study of medicine, he himself wrote nothing on this disease. It was not until a hundred years later that John Hunter gave a careful description of the symptomatology of cancer. So that the clinical study of

cancer is confined to the last two hundred years.

The clinical study of cancer involves a consideration of the etiology, symptoms, physical signs, and the treatment of this disease; but the symptoms and physical signs are so familiar to all, and the time allotted me is too brief to take up that part of my subject.

Etiology.—The theory of the ancients was that the predisposing cause of cancer was a degeneration of the blood due to a faulty diet, a morbid affection of the liver, and a weakness of the spleen. That the active cause was the accumulation of the humors of the body in some part, or the suppression of some accustomed evacuation, as the menses in women, and of hemorrhoids in men. That the humors thus shut up in the body generated tumors, that these tumors might become scirrhous, and that these scirrhous tumors might degenerate into cancers.

After Harvey's discovery of the circulation, the blood was regarded as the source of cancer. After the discovery of lymph in the early part of the eighteenth century, this was regarded as the true source of all tumors. Hunter believed that the coagulable lymph possessed the cancerous property. Müller called this coagulable lymph of Hunter, "Blastema," and this term was employed by Rokitanski and other writers until the time of Virchow, when the hypothetical blastema passed finally away to give place to the cell theory of disease, "*omnis cellula e cellula.*" Cohnheim's modification of Virchow's theory is that the only cells capable of originating neoplasms are superfluous cells sequestrated during a very early period of embryonic life. The two theories of to-day as to the origin of neoplasms are based on the cell theory and the germ theory.
